6. The microscope is of great value, especially as indicating whether dressing methods may prove valuable. I had one sample of complex-ore in which the minus 200-mesh grade showed under the microscope an intimate mixture of blende and galena. Such a mixture could not be separated by concentration.

Golden, Colo.

**L. S. Austin**.—In addition to defining "complex ores" as mixtures of base-metal sulphides, I might further limit the definition to cover mixtures, in the treatment of which the extraction of one metal interferes with the recovery of another. Thus, a lead or copper ore containing gold and silver only, while complex, presents no difficulty in the extraction and separation of its constituent metals. Again, an ore that is a combination of chalcopyrite, pyrite and galena, with gold and silver, should, after roasting, be quite suited to blast-furnace treatment. But the complex ore regarding which the question of treatment has been in dispute, appears to be one containing zinc as blende, in addition to the sulphides noted above.

Practically, either in copper or lead smelting, zinc is a detriment and so is penalized. After roasting, such an ore can be treated in the blast furnace, but the zinc is never recovered. It principally enters the slag; in part it goes into the matte, and in part is volatilized, forming accretions in the shaft of the furnace. In consequence of its volatile nature it takes away silver that should have gone into base bullion or matte. In silver-lead smelting, with a charge high in zinc, one has to modify the type of slag, making it more irony and less silicious than if it were zinc-free; and so, where fluxing iron cost money, zinc stands for a higher smelting expense per ton of materials of the charge. To keep such a slag fluid requires a little more fuel. In smelting copper ores the same drawback occurs, though in less degree, since the zinc is more easily volatilized. That the presence of zinc constitutes a real detriment is shown, in that in Colorado it is penalized when the ore contains over 10 per cent., at the rate of 50 cents per unit (1 per cent). In Utah zinc is free up to 10 per cent, and sometimes to 17 per cent; above that limit a penalty of 30 cents per unit is incurred.

To aid in the solution of the difficulty in the reduction of zinc-bearing lead sulphides, the United States Smelting, Refining & Mining Co. have in operation at their Midvale plant a concentrating mill where they separate the lead, and from the concentrates made in the wet way, the zinc by the Huff electrostatic machine. For ores suitable to this method of concentration they will then pay as follows:

For metals, the gold at $18.00 per oz.; 80 per cent of the silver at the New York market price; 80 per cent of the lead at that market price per pound less $1\frac{1}{2}$c. Ten per cent of silica is charged for at 12c per unit or $1.20 in all; 60 per cent of the iron is paid for at 6c per unit, and 30 per cent of the zinc at 2c per pound.

In silver-lead smelting, copper, when present in the ore, goes into the matte, and is in consequence recovered. In copper smelting, on the other hand, if lead is present it is volatilized and no attempt is made to recover it—it is a complete loss. Provided it is primarily a copper-bearing ore, this loss need not be a serious one, and it is better to lose two or three per cent of lead rather than to adopt some special process to recover it, or attempt to send it to some silver-lead works to obtain such recovery.

In the year 1903 the American Smelting & Refining Company smelted ores of a gross metal value of $33 per ton. At the end of. 1911 they were treating ores of an average gross metal value of but $16 per ton, some of course high in zinc. When we consider that from this value of $16 is to be taken the cost of mining, freight and treatment there seems but little margin to compensate the mine owner.

Mr. Johnson, of the Continuous Zinc Furnace Co., has lately been bringing to our attention his electric process for the recovery of all the metals in a complex ore, containing not only the base metals, zinc, lead and copper, but the contained silver and gold as well. He has done this with a great degree of success, but at a cost of $10 to $12 per ton. Now it is obvious that the complex ores awaiting new methods of treatment "of which millions of tons exist" would not stand such expense for treatment, and it would probably be found that their contained metals would not aggregate in value a figure that would bring them in the category of ore, if such a mineral were to be defined as one commercially profitable.

As an evidence of the complexity of many ores treated at custom silver-lead works, let us consider the constitution of the copper-lead matte produced by them. This matte when produced is roasted, sintered and again returned to the furnace. Each time it goes through the furnace it picks up impurities from the charge. Finally, when its copper content has reached a proper figure, it is withdrawn from the circulation, separately smelted to yield a matte of 40 per cent or more copper, and sent to a refinery for converting, yielding blister copper and bag-house fume.

An average analysis of the matte is as follows: Pb, 26.9 per cent; Cu, 43.1 per cent; Ni and Co, 0.4 per cent; $SiO_2$, 0.3 per cent; Fe, 8.0 per cent; Zn, 2.5 per cent; S, 15.5 per cent; As, 1.7 per cent; Sb, 0.76 per cent; together with Au, 0.17 oz. and Ag, 98.1 oz. per ton.

The fume yielded in converting is found to contain: Pb, 52.5 per cent; Cu, trace; Zn, 3.0 per cent; S, 5.4 per cent; As, 14.2 per cent; Sb, 1.6 per cent; Te, trace; and Ag, 10.0 oz. per ton.

Thus, besides the metals we expect to find, there is present in the matte nickel and cobalt as well as arsenic and antimony; in the fume are both of the latter metals, a trace of tellurium and much arsenic. All these metals are detrimental, and when in sufficiently pronounced quantities are penalized. Another metal, more volatile than zinc, and entering the bag-house fume of the blast-furnaces, sometimes to the extent of from 15 per cent to 20 per cent, is cadmium, not to mention arsenic. Since the flue-dust goes back to the blast-furnaces for the recovery of lead, these metals continually climb to higher percentages in the closed circuit until, like an electrolyte, they must be removed for special purification.

There is no question to my mind, that with the advance of metallurgical methods, the day will come when many of these low-grade ores will be commercialy exploited, but the day is not yet. In looking for the best methods of treatment no doubt microscopic as well as chemical methods of analysis will be of much aid. In what directions reduction methods will develop it would be hazardous to suggest, but as I believe, not in the line of pyrometallurgy.

Salt Lake City, Utah.

**Edward S. Wiard.**—There is a complex-ore problem. I would define a complex ore as a mixture of two or more base-metal sulphides in gangue, at least two of which are of commercial value.

Present results from the treatment of such ores would be improved by skilled operators. There are no new methods in use at present, but it might confidently be expected that improved processes would arise from a more refined employment of present methods.

The number of available mines with complex ores, now idle, from which refined methods of ore treatment would win a profit is small, but they do exist.

A difficulty encountered in treating these ores is that the commercial sulphides have too nearly the same specific gravity. As the minerals become more finely disseminated they become more refractory. Refractoriness in such ores may be said to be represented by the product of the first factor times the square of the second.

In my opinion, mechanical processes will be more generally applied in the treatment of these ores.

The use of the microscope in connection with complex ores will be of value only as it gives better vision than can be had with the naked eye.

Denver, Colo.

**R. C. Canby.**—1. Literally speaking there is undoubtedly a "complex-ore problem" as applied to ores such as those to which your terms have reference; that is, the base-metal sulphides, especially where these sulphides are so finely disseminated as to require particularly fine grinding to separate the different sulphides from one another. More broadly speaking, however, the entire field presents problems, the gradual mastering of which is bringing under profitable treatment ores which were previously of no commercial value. Such a base-metal sulphide would be "complex" when containing zinc, especially in combination with copper, particularly when the sulphides are finely disseminated.

2. Strictly speaking the amenability of these ores to present processes is not a question of operating skill.

3. Many mines are now operating at an economic disadvantage, and there are also many deposits which will eventually develop into mines as metallurgical progress is made.

4. In the ores referred to, it is unquestionably the sulphide of zinc which renders them "refractory." It is not altogether, however, owing to the difficulties arising from the presence of the zinc which calls for a more suitable method, but because in the usual treatment of such complex ores, at present, the zinc content not only incurs treatment penalty but is also lost, either in the concentration or in the smelting.

5. Of the new or unusual methods, "flotation" is already producing enormous quantities of zinc heretofore lost, and is making possible sulphide savings which were previously impossible. Flotation, like other forms of mechanical concentration, however, is only a partial or preparatory step. Gradual improvements in the methods of smelting these concentrates will be made to suit the various products and local conditions. I am inclined to believe that electrometallurgical treatment will be brought about eventually through the development of hydroelectric power, making cheaper power available.

6. Microscopic examination of finely disseminated sulphides reveals much of interest, not only as to the minerals present, but as to the mineralogical history of the ore. It seems that the microscope is, however, more interesting to the mineralogist than to the metallurgist. Minerals so finely disseminated as to become microscopic evince their close dissemination by a more cursory examination than that of the microscope.

Miami, Ariz.

E. L. Godbe.—1. Unquestionably there is a "complex-ore problem." In the generally accepted sense, a complex ore is one containing a very fine and intimate mixture of base-metal sulphides, principally, zinc, lead and iron, the separation of which is difficult or impossible by gravity methods of concentration. Many other ores are complex in their nature, by reason of the fact that well known metallurgical methods will not work them to advantage, yet these are not generally regarded as coming under the caption "complex ores."

2. In the very large majority of cases, the so called complex ores, I think, are amenable to present processes, and the only thing necessary to apply them profitably is metallurgical skill in working out the various details, the shaping of economic conditions, and in the acquisition of sufficient capital to construct proper plants. The average mine operator is very skeptical in regard to the adoption of new methods, owing to the fact that so much money has been lost in untried and impractical processes in the hands of unskilled metallurgists. On the other hand, there are certain ores the minerals of which are so intimately associated as to be almost chemically combined, and for this kind of ore there seems to be little doubt but what new methods will have to be devised.

3. There are a great many mines scattered throughout the West which can produce a very large tonnage of complex ores, and very profitable results will follow the adoption of suitable methods of treatment. In order to work out and solve these problems the most essential thing, in my opinion, is careful experimentation in the hands of competent metallurgists. The great difficulty experienced so far in the working out of these problems is the inability to find properly equipped laboratories where all the known methods of treatment can be tried on any particular ore. As every one has its own peculiar characteristics, no operator can tell how any process will work, except by trying it, and it is safe to say there is not a single laboratory in the United States where all of the various known methods of treating complex ores can be definitely tried out. If the miner could take his ore to, say a first-class government laboratory, one that is thoroughly equipped with facilities for testing out all of the modern improved methods, such as flotation, roasting, wet and dry separation, gravity concentration, to say nothing of the still newer methods such as volatilization of sulphur, reduction of the metals to the metallic state with subsequent concentration, volatilization of zinc and lead and condensation in the metallic as well as the oxide form, etc., there is little question but what a satisfactory solution of almost any complex-ore problem could be found. Furthermore, the report of such a laboratory would enable a mine owner to acquire sufficient capital to build proper reduction works. After having been once installed, a laboratory of this character should be self supporting.

5. For the real complex ores, without doubt, the mine owner will have to look to the hydrometallurgical and electrometallurgical methods for relief. Great progress is constantly being made in the development of these processes, and while to-day it cannot be said that any one of them is an established success, yet they certainly do give bright promise for the future. There are so many methods suggested along these lines, the application of which will doubtless be confined to certain particular kinds of ore, that it would be difficult to say just which ones present the greatest promise. As electricity is rapidly becoming an important factor in almost every hydro-metallurgical process, it is safe to assume that its use will largely increase.

6. Microscopical examination would undoubtedly greatly facilitate the diagnosis of any particular ore, but in itself I do not think it will play a very important part. In my opinion, what is most needed to solve this complex-ore problem is properly equipped laboratories, competent operators, plenty of money for experimentation, intelligent working out of economic conditions, and, last but not least, more faith on the part of mine managers and owners.

Salt Lake City, Utah.

---

**A Manual of Electrical Testing** is the subject of a new forty-eight page bulletin, size 8 x 10½ in., issued by the Wagner Electric Mfg. Company of St. Louis. Besides describing the line of portable instruments manufactured by the Wagner company, this publication describes various types of electrical instrument movements, the errors to which they are subject and gives suggestions for their handling and care. The methods of making electrical test on alternating-current and on direct-current motors and generators and on transformers are described at length and illustrated by comprehensive and instructive diagrams.

# The Metallurgical Engineer in the Steel Works

BY JOHN HOWE HALL

In their attitude toward the employment of metallurgical engineers, managers of shops may be roughly divided into three classes: those who utterly disbelieve in metallurgists, those who employ one for show purposes, but pay no attention to his recommendations, and those who believe that his efforts, properly directed, are of value.

Managers of the first class say "Look at so-and-so, who worked up from the bottom and ran the great shops at such-a-pace! You didn't catch him bothering his head with fellows with 'highfalutin' notions. Practical man, he was, and employed only practical men!" Of course, there are at least two points in the case of their hero that they overlook. First, he made his way to the top in pioneer days, when the margin of profit was large and expert knowledge limited; second, in his later career, it is a hundred to one that the great magnate made use of the services and advice of experts in various lines, in order that his shop might continue to make money in times of increasing competition and decreasing margins of profits, and to keep abreast of its competitors in the quality of its output.

In dealing with managers of this class one hears the words "Practical Man" about every third sentence. The definition of a practical man seems to vary more widely than any known variable in a steel works. Reduced to its lowest terms and defined by negative methods, it appears that to a great many managers any one who submits for consideration a proposal based upon a reasoning process which the manager does not understand, is *not* a practical man, and should be treated accordingly.

The second class, fortunately rare, is composed of those who do not believe in metallurgists, but who see successful shops employing them, and in order to gain a reputation for progressiveness, engage an unfortunate individual to play by himself in a corner and be exhibited with a flourish to visitors—"Our research laboratory, you know, where our new processes are worked out." The vistor is much impressed. Managers of this class take such elaborate precautions to keep the metallurgist from all contact with the actual routine of the shop, as to give the impression that they would be pained and grieved if the unfortunate man actually succeeded in surmounting the barriers raised around him and contributing something of value to his employers.

Coming now to those who believe that the metallurgist can be made of value to his employers, we find wide differences of opinion as to how he should be made use of. To take the widest extremes, let us consider the manager who believes that his metallurgist is of value only to conduct "post-mortems" upon material that has failed in service, and the manager who believes in obviating the necessity of post-mortems. It is often said that the methods of the metallurgist are of value only as a post-mortem. Stripped of the specious pleas that always accompany the statement, this means that the knowledge that is capable of explaining the failure of a piece of work, could not have foreseen that failure if applied to the object before it was shipped. We see at once that if this is true, then it must be a fact that all causes of failure are so hidden in the objects manufactured that they can not be detected without destroying the objects. It requires but a slight stretch of imagination to see how false is this assumption.

The causes of failure in service will be of two classes, those that could have been discovered by examination of the material before shipment, and those that could not. In addition, of course, there will always be the "mysterious" failure to which we shall refer again a little later. Granting that the metallurgist should only conduct post-mortems, ascertain the causes of failure, and point them out to his employers, on whom is to fall the burden of making sure that the product thereafter is free from the defects that have been found to cause failure? For unless failures are to be lessened, surely the post-mortem itself is a waste of time and money. There is no profit, and but poor consolation, in knowing why a piece of work failed, unless we hope to prevent the failure of other pieces from the same cause.

Many of the causes of failure disclosed by post-mortems are of a nature that only the expert can apprehend. How shall the practical men in the shop be able to recognize them in the future, and guard against their recurrence? Again, if the cause of failure be plain to the ordinary shopman, how far can we rely on his intelligence to understand the necessity of condemning the material suspected? His job is to produce the maximum tonnage of material fit to ship; the more material is condemned, the less his output. Hence his whole mental attitude is such that he is sure to throw the weight of his influence toward shipping everything that passes a casual inspection, and taking chances on the issue. Both by training and by inclination, he is the man of all men about the shop who is least likely to be active in condemning poor material.

It is evident, then, that the man who conducts the post-mortems should be in a position to recognize defective material before it is shipped—if possible before it is finished. To ensure this, all processes in the shop in which inferior work may be done, *must* (not may) be subject to his check.

Moreover, there is another side to the question. In conducting a post-mortem, a man who does not have at his disposal a mass of data on the properties of the materials the shop manufactures, is forced to rely solely upon a general knowledge of the subject, based upon the work of independent investigators, which is all too scanty, and in but few cases applies directly to the problem in hand. It is then almost impossible for him to ascertain the true cause of the failure. Here we see one of the serious disadvantages of relying upon examinations of failed material, made by an expert who may be a thousand miles away, and familiar only in a general way with the materials the shop produces. His opinion is necessarily couched in rather general terms, often covering several possible causes of failure, because in most cases he cannot be really sure of the exact one. He fires a shotgun into the flock, as it were, instead of picking out with a rifle the particular bird that is doing the damage.

In order to form an opinion of value from a post-mortem, therefore, the metallurgist must have data as to the nature of the material which the shop has been producing, and as to its behavior in service; and in order to apply the conclusions obtained from a post-mortem to the material being made, that material must be constantly subject to the metallurgist's check. Thus either way we look at the matter, we see that the three functions of the metallurgist are inseparable one from the others. He must conduct post-mortems on failures, check the material being manufactured, and apply the knowledge gained from both sources to the improvement of the product. The material that can be recognized as liable to failure from a cause identified by post-mortems, can then be held up, and its failure prevented; and by tracing to their origins both this class of defects and those that cannot be recognized by an examination of the material before shipment, the failures of both classes can be minimized.

The "mysterious failures" will at first be numerous. It will be found, however, that by keeping a full record of them, and by having them constantly in mind, they will soon be recognized as falling into several classes. As data from the examination of material before shipment accumulates, light will be thrown on the causes of more than one class of unexplained failure, and the number of kinds of mystery will be greatly reduced. It may safely be said that the greater number of unexplained failures are "unexplained" solely from lack of systematically collected data upon which inferences may be based.

It is plain that if the metallurgist's services are utilized in this manner, he will work in collaboration with the manufacturing department, the claim agent and the engineering and sales departments. The routine of the activities under his control should be so arranged that the manufacturing department must submit daily to his inspection tests taken from the product itself or from coupons, that shall cover the operations of the day to a sufficient extent to guard against the possibility of the shipment of a lot of defective material. The defective material brought to the notice of the claim agent must be examined, and the cause of failure ascertained and traced to the operation responsible for the trouble. The daily testing of current product and the examination of material that has failed in service, will suggest many improvements in both processes and product. The metallurgist will co-operate with the manufacturing department in making these improvements, and with the engineering and sales departments in the marketing and utilization of improved material.

Some managers install apparatus for microscopic examination and physical testing of their material, and put it in charge of a young man without technical training. He is the information-gatherer, and his reports are forwarded to someone higher up, generally the superintendent of the shop. The latter is often too busy to use the information to the best advantage, and in many cases lacks the technical education and training requisite to a proper understanding of the problems brought up.

Again, a young man from college, with a good technical education but no experience, is given charge of the metallurgical work. Until he has acquired the necessary practical experience, the conclusions he may draw from his work are of but little actual value, for he is sure to "go off at half cock" every little while; and in a laboratory, practical experience is absorbed slowly.

The best advice to give a technical college graduate who wishes to be a metallurgist is to put on overalls and work two or three years in the shops. For a while he will learn new facts so fast that he will feel almost contempt for the technical knowledge acquired in college, and will think "Yon Yohnson" knows more than Professor So-and-So. Then he will begin to see Yon's great limitations, as well as the undoubted value of his practical information, and with the two kinds of knowledge he has acquired, will gain an understanding of the inwardness of steel works operations that will be invaluable to him and to his employers.

Such a man in a large works can be employed constantly, overseeing the activities of a number of assistants, and with plenty to keep him more than busy. The small shop, on the other hand, cannot afford to pay a salary such as this man is capable of commanding. They must, therefore, employ a younger man, college graduate or home trained, to carry on the routine work, and engage an experienced metallurgist to map out the work in the first place, to consult with the management in interpreting the results and making the changes in shop practice that may be found necessary, and perhaps from time to time to extend the activities of the metallurgical department.

Such an organization can be as simple or as elaborate as the size of the shop and the diversity of its output necessitate. It may include only the daily or weekly testing of a few samples by the chemist in his spare time, or even by an outside firm who will take the work at a fair price on a yearly basis; and at the other extreme, it may include the employment of a large staff under the direction of a resident metallurgical engineer. To-day, with the great increase of our knowledge of iron and steel and the growing demand for superior products, it is a very small shop indeed that can afford to dispense with the systematic checking up of its output by technical men of knowledge and experience, along the lines here suggested.

New York City.

---

The Eastern Tanners Glue Co. of Gowanda, N. Y., which ranks as the largest glue factory in the world, has just put in a third Swenson evaporator for making glue. This is the largest of the three outfits in the plant. The Eastern Company is noted for its labor-saving devices, including automatic industrial cars which take a certain number of hides directly from the railroad spur, stop at any predetermined vat, dump the hides into it, and then return automatically to the place of loading, alongside the railroad car. Due to the extensive use of such devices all over the plant, this company has found it possible to make glue at so low a figure that some other manufacturers, in order to tide over a sudden demand beyond immediate capacities, are said frequently to purchase glue from the Eastern company at a figure not higher than their own costs.

**The attitude of the Canadian people** toward the development of radium in the Dominion is reflected by the action of the provincial governments of Ontario and British Columbia. In the former, a legislative bill provides for a reward of $25,000 to the first person who discovers radium in the province in sufficient quantity for commercial extraction. The bill also authorizes the government to reserve all radium in Crown lands, with the right to work deposits, and install necessary equipment and plant. The sale of radium is to be conserved and regulated by the government. In British Columbia the prize offered for discovery of radium is $5,000, and a reserve is placed on all public lands in which radium may be found. The bill provides for regulation of the radium industry, and for a retention by the Crown of a 50 per cent interest in all radium produced.

**The newly formed Chicago Section** of the American Institute of Mining Engineers held its first annual dinner and meeting at the Sherman House on the evening of April 14. The officers elected were: Chairman, Robert W. Hunt; vice-chairman, J. C. Ede; secretary-treasurer, H. W. Nichols; executive committee, F. K. Copeland and G. M. Davidson. The next meeting will be in May.

# Cascade Attachment for Graphite Furnace *

BY EDWIN F. NORTHRUP

If a cubical space, in which the atmosphere cannot circulate, contains graphite and is brought, by an input of electrical energy, to a temperature in the neighborhood of 1000 deg. C. or more, the atmosphere in this space becomes converted into an atmosphere which is chemically inactive in respect to graphite. If a graphite resistor, through which a separate source of current may be run, is centrally located within this space it may be brought, by an input of sufficient electrical energy, to a temperature little short of the vaporization point of graphite without any observable chemical reaction of the resistor with the atmosphere. The resistor is quite as inert as if located in a perfect vacuum. Furthermore, since experiments show the above statements to be true, the idea is at once suggested that, if the cubical space be made of steel walls capable of sustaining a pressure of many atmospheres, the vaporization temperature of graphite would be greatly raised and thus enable the artificial production of temperatures exceeding considerably the temperatures of the carbon arc.

As everything tends to evaporate more readily with diminution of pressure, it seems to the writer that the use of a vacuum furnace for obtaining the highest temperatures is a step in the wrong direction, and that it would be better to aim at obtaining a furnace in which the pressure might be made very great, and the atmosphere made absolutely inert by electrically heating comparatively large masses of graphite to a moderate temperature. One may then obtain the desired maximum temperature by a rapid input of a large amount of energy in a small and centrally located resistor unit.

These ideas have been tested by the writer at atmospheric pressure with complete verification. He hopes the opportunity may offer for carrying out similar experiments at enormous pressures.

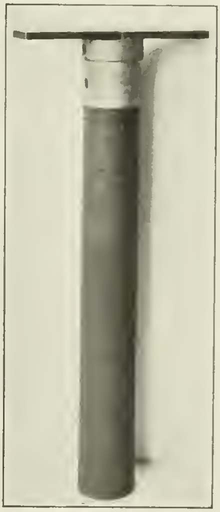

FIG. 1—CASCADE ATTACHMENT WITH ALL PARTS ASSEMBLED

The device, which this article describes, easily melts tungsten and gives a temperature, without perceptible depreciation of the graphite resistor unit used, which certainly exceeds 3000 deg. C. It is placed in and fills the chamber of the high-temperature graphite furnace described by the writer in the January, 1914, issue of this journal. The large furnace is first brought to a temperature of approximately 1600 deg. C. and then by means of a switch the energy (obtained from the same transformer) is transferred to the heating element of the device. This heating element is a slotted tube of re-graphitized Acheson graphite. The internal chamber, which acquires a perfect black body temperature exceeds 3000 deg. C. (or less if desired), is 15 cu.c. As the temperature is produced in steps falling from a maximum temperature in an inner chamber to a lower temperature in a furnace chamber (into which the device is readily fitted or removed), the writer has called it a "cascade" attachment.

The high temperature attained in the cascade attachment with energy obtained from a single transformer, is made possible, first, because the chamber of the large furnace develops an atmosphere which gives absolutely complete protection against chemical action with graphite and, second, because the energy yielded by the transformer is first accumulated and stored in the refractories of the furnace of large heat capacity, and then additional energy, before the furnace cools much, is concentrated in a relatively small heating chamber.

The cascade attachment consists of a graphite tube which fits the furnace chamber, of two massive graphite terminals or electrodes, two nickel-plated iron terminals, a furnace cover and head piece of refractory material and a replacable resistor-unit of Acheson re-graphitized graphite. There is also inserted through the bottom of the graphite tube a graphite plug which holds a replacable crucible of graphite (or any other material) and a graphite tube which surrounds the resistor-unit and shields the walls of the furnace chamber from the intense radiation which proceeds from the resistor-unit. Fig. 1 shows the cascade attachment with all parts assembled and ready to place in the chamber of the furnace and Fig. 2 the same with its parts unassembled.

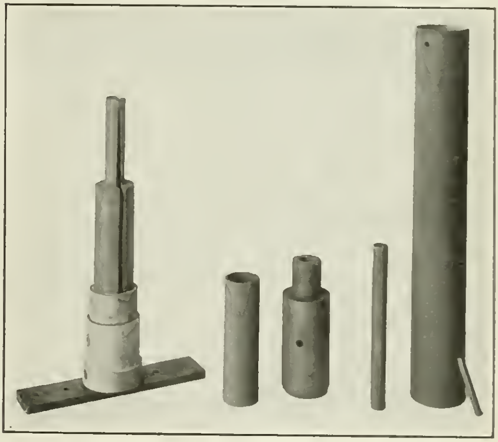

FIG. 2—PARTS OF CACADE ATTACHMENT UNASSEMBLED

The life of all the parts, except the resistor-unit, is indefinite. The resistor-unit is made to be readily replacable and is an extremely simple and inexpensive device. It consists of a tube of re-graphitized Acheson graphite, of which 7.6 cm of its length becomes heated. It is 1.55 cm internal diameter and 1.75 cm external diameter. This tube, which is slotted on two sides, slips into cuts in the massive graphite electrodes where it is held in position with two graphite screws. The crucible is a cylinder about 1.05 cm internal diameter and 7.6 cm deep. When in position it nearly fills the chamber of the resistor-unit.

To use the cascade attachment one proceeds as follows: The crucible is removed through the hole in the bottom of the cascade attachment and filled with the material which is to be submitted to the high temperature. The crucible, filled with its charge, is then replaced in the cascade attachment and held in its proper position by a graphite pin provided for the purpose. The cascade attachment is then lowered into

---

*The furnace referred to is the one described by E. F. Northrup under the title, "A New High Temperature Furnace," METALLURGICAL AND CHEMICAL ENGINEERING, January, 1914.

the furnace chamber. The heavy leads which are provided are fastened with thumb screws to the iron terminals of the cascade attachment. The other ends of these leads are attached to two poles of a double-pole, double-throw switch. The furnace terminals are attached to the remaining two poles and the transformer secondary terminals are attached to the middle point of this switch. The outfit is now ready to heat. The switch is thrown to "furnace," the voltage handle of the transformer is thrown to the stud giving highest voltage and the furnace is heated rapidly with an input of about 5 kw. While the transformer is nominally a 4-kw transformer, this output is for continuous operation and the transformer is not in the least strained when made to yield 5 kw for one or two hours nor by being made to yield 8 kw to 9 kw for five to ten minutes. When the current has been on the furnace for about seventy-five minutes, a temperature of about 1600 deg. C. being obtained, the switch handle is thrown to "cascade." The resistance of the heater-unit has been so chosen that the cascade attachment will take about 8 kw.

Several experiments with the cascade attachment were made by the writer. It required a number of trials to determine the proper dimensions and resistance of the cascade resistor unit for obtaining the highest temperature with the transformer employed.

A test was made April 1 to determine how long it would take and what energy would be required to bring to complete fusion a No. 20 tungsten wire. A piece of wire about 40 cm long was made perfectly straight. One end of this wire rested in the center of the bottom of the crucible and the other end projected through a hole about 1 cm in diameter in the top of the cascade attachment. The wire was centralized in this hole by means of a small plug of refractory with a hole in its center through which the wire would pass easily. At the instant a melt occurred the fact would be made evident by the wire sinking vertically downward into the crucible. The observations actually taken are directly transcribed in the table at the end of article from the writer's note book.

A curious and unexplained phenomenon was noted. Shortly after, but not immediately after, the switch was thrown to "cascade" the furnace developed a roaring noise. This noise increased in volume and became very loud before the wattmeter indicated any increase in power input. It was not due to an arcing, as no arcing occurred. In this test the wattmeter was placed on the primary side of the transformer and, on account of losses in the transformer and secondary leads, it is thought about 10 per cent should be deducted from the wattmeter readings when the switch was on "furnace" and about 15 per cent when the switch was on "cascade."

The following data are of interest: The average input (actual) on the furnace was 4.3 kw. The time of this input was fifty-three minutes. The total input on the furnace was, therefore, 3.8 kw-hours. As the outside of the furnace was still cold to the hand practically all of this energy was stored in the furnace. The average input on the cascade was 7.1 kw and the time of input on the cascade totaled 5.7 minutes. Therefore 0.675 kw-hours of additional energy was delivered to the cascade. The last time the switch was thrown on cascade the average input was 7.1 kw for 2.2 minutes, making 0.26 kw-hours input of energy which was required to bring about 15 cu. cm of space to the melting temperature of tungsten when the temperature of the furnace chamber was, by estimation, about 1600 deg. C. The outside area of the cascade resistor unit was 41 sq. cm. At the time tungsten melted 197 watts per square centimeter were being supplied to the cascade resistor unit. The volts at the cascade terminals were 28 and, by calculation from the input, the cascade resistor unit must have been taking 295 amp. The resistance of the cascade resistor unit, including its contact resistance with the graphite electrodes, measured 0.126 ohm at room temperature. Its calculated resistance when tungsten melted was 0.098 ohm, a decrease from cold to hot of about 22 per cent. The above figures must not be taken as very precise because the wattmeter registered the power input on the primary side of the transformer and because contact resistances may have amounted to several per cent of the total cascade resistance.

An examination next day of the resistor unit showed that it had suffered no deterioration. Its surface presented a satin-like appearance which showed, under the lens, that a slight vaporization from the graphite surface had started.

April 1, 1914. Observers—E. F. Northrup, Mrs. E. F. Northrup.
Test of cascade furnace after alterations.
Resistance of cascade attachment = 0.126 ohm.
Measuring current 10 amperes. Resistance decreases slightly with increase of measuring current.

**Vismera Pure Iron** is the title of a booklet issued by the Inland Steel Co., of Chicago. Vismera pure iron is 99.86 per cent pure iron guarantee, has high tensile strength, perfect physical structure, and is rust resisting. The following analysis is said to represent regular practice: iron 99.882, no silicon, no copper, no aluminium oxide, 0.040 C, 0.004 P, 0.020 S, 0.040 Mn, 0.001 H, 0.009 g, 0.004 N. The total impurities are therefore 0.118 per cent. Vismera pure iron is made in black sheets, galvanized sheets, corrugated sheets, roofing sheets, sheared sheets, etc.

The **Mountain Copper Co.** will install two 8 ft. x 36-in. cylindrical herringbone gear driven Hardinge mills in their new concentrator at Keswick, Shasta County, California. The Miami Copper Company are at present installing additional Hardinge mills.

**Pyrometer Facts** is the title of an interesting little bulletin issued by The Stupakoff Laboratories of Pittsburgh, Pa., giving illustrated notes on the thermo-electric pyrometer, the wall-type galvanometer, the shelf-type and portable test galvanometer, the recording pyrometer, the "simplex" base-metal portable pyrometer, the platinum, platinum-rhodium thermocouple, the base-metal thermocouple, water jacket compensation.

**The Bethlehem Steel Company** is putting up a Cottrell plant to purify blast furnace gas.

# The Igneous Concentration of Metallic Values from Mixed Sulphides—II

## Utilizing the Fuel Value of Sulphides to Make a Sublimed Zinc Concentrate

BY F. L. CLERC

In a previous paper[1] on this general subject I have outlined the progress of the application of the pyritic idea to the metallurgy of copper, accepting the definition of a pyritic process to be one in which the heat generated by the rapid oxidation of metallic sulphides by an injected air blast is utilized to take the place of heat developed by carbonaceous fuels. The sulphides oxidized may be contained in ores as sorted at the mines, or in the mechanically dressed products of concentration, or in intermediate products of smelting operations. I have expressed the opinion that zinc smelters may profitably apply the same idea to the concentration of zinc in some ores low in zinc, forming a sublimed product rich in zinc, corresponding to the rich mattes produced by copper smelters.

This historical sketch, traced out by means of a selected class of events, namely, commercial tests on a working scale which have been carefully observed and recorded, is of interest to anyone who wishes to extend the application of the pyritic principle into other fields of metallurgy.

The main facts brought out may be reviewed. The first working test I have quoted was preceded by a long line of laboratory experiments which had determined chemical facts and measured physical constants with great precision. The results of this laboratory work take high rank as contributions to human welfare; they were essential to any industrial application. With these data at hand, small scale metallurgical laboratory experiments were tried, to solve one or more problems involved in industrial enterprises.

A striking feature in this development is the fact, clearly shown, that many years elapsed after a practical and public demonstration of the merits of the process before it was successfully introduced in practice. Still other concurrent conditions were requisite to secure its establishment on a firm basis. These were: an available supply of suitable ores, and, not less important, trained metallurgists who saw a value in the process and were able and willing to tackle and overcome the constructional and manipulative details incident to all new metallurgical processes.

The process was first introduced at particularly favored localities. The discussion of the subject by American metallurgists[2] shows in what measure the process was utilized under less favorable conditions and indicates the modifying effect of local conditions.

Before attempting to employ the process in zinc metallurgy, its development in copper smelting should be carefully studied.

### Data Available and Required

Fortunately, the chemical and physical data are readily available. Some laboratory experiments are desirable in working out some of the problems involved. With the great extension of facilities for this work furnished by government, university, corporation, and private metallurgical and test laboratories, it is to be expected that this need will be recognized and filled. Some of the determinations required reach to the very essence of pyritic smelting, and will supply much needed data; for example, the determination of the effect of increasing the temperature of blast and of the rate of blowing; the composition of issuing gases; the fusibility of definite charge mixtures; the separation of matte, and the expulsion of zinc from slag and matte.

### Experimental Apparatus Suggested

I subjoin for present reference a few constants involved in the study of pyritic smelting, and submit several sketches illustrating simple laboratory apparatus by means of which many results of value should be obtained. Anyone accustomed to laboratory experiments can readily improve upon the construction shown. I hope the ideas involved will be suggestive of such improvements. Fig. 1, mainly diagrammatic, shows an air meter with a tightly fitting piston, the displacement of which is read on the graduated piston rod. The pressure is regulated by the weight applied to the cross-arm, which carries the guides to ensure parallel motion. Connected with this is the blast pipe *D* containing a thermometer *E* and a pressure gauge *F*, which may be a spring gauge measuring ounces, or a simple tube measuring inches of waterhead; beyond these, on the pipe line, should be located an electric heater for the blast, shown separately at *N*, and a thermopile, represented by *O*, to measure the temperature of the heated blast. With a proper gas valve in the air pipe beyond this, and the ordinary ammeter and voltmeter connected with the electric heater, the efficiency of various electric heaters, as affected by the volume of the blast, could be readily measured. This apparatus, connected with the inner crucible *H* would be sufficient to conduct many experiments in sinter-roasting, clinkering and volatilization on commercial grades of ores, as well as on selected mixtures, with and without additions of carbonaceous fuels and fluxes. The crucible *H* should be inclosed in a larger crucible and the space between them packed with a heat insulator. The detached cover *J* of the inner crucible, with the goose-neck *K*, the equalizing tube *L* and the discharge tube *M* shows the manner of drawing off the

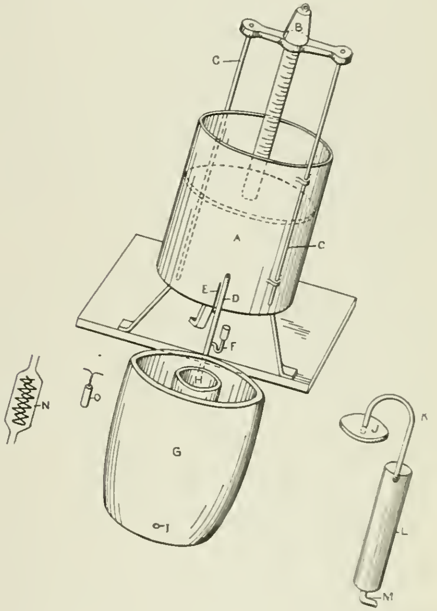

FIG. 1—APPARATUS FOR STUDY OF PYRITIC PROCESSES

evolved gases and sublimation products for analysis.

---

[1] This journal, April, 1914, p. 250.
[2] Pyritic Smelting, *Eng. & Min. Jnl.*, Oct. 10, 1903, et. seq.

A better arrangement for the inner crucible is shown in Fig. 2, where it is set in a sand-bath held in a metal pan, and is surrounded by a non-conducting cylinder notched at the bottom to slip over the air and tapping pipes. The space between the crucible and cylinder should be filled with mineral wool or other heat insulator. The sand-bath forms a good seal to the space between crucible and cylinder, and it should be heated externally to about the temperature of the gases issuing from the top of the crucible, to overcome the excessive radiation from the small apparatus employed.

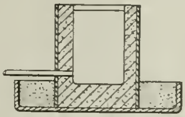

FIG. 2—ARRANGEMENT FOR INNER CRUCIBLE

Fig. 3 shows a better form of air meter, and there should be two of them, with alternate connections; so that while one is being emptied, the other could be filled from an air pump or blower.

Fig. 4 shows an arrangement of crucible for a melting charge, furnishing bullion, matte, or slag, or all of them, by means of which the melted product is removed from in front of the tuyeres. *C* is a lower crucible answering the purpose of a fore-hearth. At the start, it functions as an air chamber on the blast system; as it gradually fills up, the air is expelled. It may be discharged by the bottom plug *H*. The function of the sand-bath *F* and the insulation around the crucible is simply to offset the excessive radiation loss from a small crucible. If its temperature is not above that of the issuing gases, the added heat has no other effect on the charge in the crucible.

### Results to Be Obtained from Experiments

With this apparatus, the operation can be made nearly continuous with a dried-out charge, and slagging and matting operations can be carried on, and the behavior of various carbonaceous fuels, charcoal, coke, lignite, and anthracite, can be observed, when added to the charge. With the whole apparatus the effect of blast temperature and of the rate of blowing can be measured with reasonable accuracy, and by analyses of the products at observed intervals, and analyses of the original charge, a control can be had over what has actually taken place in the furnace.

The results of these measurements cannot fail to be of value to metallurgists having to do with desulphurizing, volatilizing, sintering, clinkering, fluxing, slagging, matting or smelting various furnace charges. These results will give some indication of the metallurgical value of various fuels, and will probably determine the lines on which the igneous concentration of zinc from mixed sulphides should be planned and undertaken on a commercial basis.

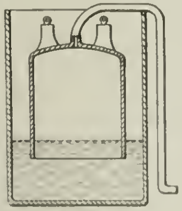

FIG. 3 FORM OF AIR METER

To get the net evolution of heat from the oxidation of a pound of zinc existing as sulphide, deduct the heat of combination of one pound zinc with sulphur, from the sum of the heats of combination of the zinc and sulphur with oxygen. With one pound of zinc there is associated practically one-half pound of sulphur. The burning of this to $SO_2$ will furnish an additional amount of 1916 B.t.u. evolved in the transformation. To get at the heat evolved per unit of oxygen, divide the heat evolved per unit of zinc by the oxygen required to oxidize zinc, called unity, plus the percentage ratio of oxygen required to oxidize the combined sulphur.

The heat of combination of definite substances is given in text books, as calculated for a different weight of each substance. These different weights are called molecular weights. That is, they are proportional to the weights of two substances which combine to form a compound.

This is a convenient form for metallurgical calculations. The metric system of weights and measures offers great facility in calculation, but because American engineers generally use the pound avoirdupois and the British thermal unit, to express the thermal value of fuels, I have arranged Table 1 in these units.

It should be explained that the figures given in all tables record the amounts of heat given out by the compounds in cooling to somewhat conventional temperatures, which may be either room temperature, or zero Fahrenheit, or zero Centigrade, or absolute zero.

In all metallurgical operations, the heat carried off in the escaping gases is necessarily lost to the furnace. In any particular case we can calculate what heat is thus lost, if we know the composition, weight and temperature of the escaping gases.

This heat they would give up in the calorimeter, if they were cooled to the starting point of the tables. Therefore, this unavoidable loss should be deducted from the values given in the tables, to get at the metallurgical value of any particular fuel. It is impossible to make tables for all temperatures of all gases, but in general the correction to be made in comparing fuel values is slight.

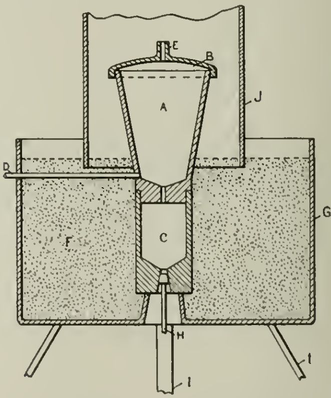

FIG. 4—APPARATUS FOR STUDY OF SMELTING CHARGES

The exception is, where a change of state occurs in one or more of the gases, at a temperature below that at which it escapes from the furnace. This change of state corresponds to the condensation of steam, which gives out a notable amount of heat that is registered in the calorimeter, but is not available in the furnace for the reason that the issuing gases have a temperature above the boiling point of water. It is proper, then, to deduct the latent heat of the water formed from the heat of combustion of carbonaceous fuels. It is well known that these fuels differ greatly in the amount of water formed by their complete combustion. A representative value of the calorific value of commercial coals must, therefore, be arbitrarily chosen.

The calorific value of any substance may be measured for a unit of that substance, or for a unit of oxygen, or of air, required to burn it. A comparison of these measures is often of interest.

In Table 2 I have deducted the heat of combustion

| Sulphur | $Cu$<br>1.988 | $CuS$<br>2.988 | 569 |
| Sulphur | $Cu$<br>3.975 | $Cu_2S$<br>4.975 | 1,142 |

TABLE II

| COMBINED WITH | | GIVES | AND EVOLVES | ALSO GIVES | EVOLVES | TOTAL | ABSORBS | NET |
|---|---|---|---|---|---|---|---|---|
| One Lb. of | Lb. of | Lb. of | B.T.U. | Lb. of | B.T.U. | B.T.U. | B.T.U. | B.T.U |
| $ZnS$ | $O$<br>0 495 | $ZnO$<br>0.835 | 1924 | $SO_2$<br>0 66 | 1285 | 3209 | 798 | 2411 |
| $FeS$ | $O$<br>0 650 | $FeO$<br>0 922 | 1343 | $SO_2$<br>0.728 | 1418 | 2761 | 491 | 2270 |

To burn completely 1 lb. $ZnS$, requires 0.495 lb. of oxygen for zinc and sulphur, and develops 2411 B.T.U. of available heat.

To burn completely 1 lb. $FeS$, requires 0.650 lb. of oxygen for iron and sulphur, and develops 2270 B.T.U. of available heat.

To burn 1 lb. of carbon to $CO_2$ requires 2.667 lb. of oxygen and develops 14,580 B.T.U. of available heat.

To burn 1 lb. of carbon to $CO$ requires 1.334 lb. of oxygen and develops 3281 B.T.U. of available heat.

It then requires about 6 lb. of $ZnS$ to replace 1 lb. of pure carbon burnt to $CO_2$, but only about 1 1-3 lb. if burnt to $CO$.

Heat developed per lb. of oxygen for $ZnS$ is $\frac{2411}{0\ 495} = 4870$ B.T.U.

Heat developed per lb. of oxygen for $FeS$ is . . $\frac{2270}{0\ 650} = 3492$ B.T.U.

Heat developed per lb. of oxygen for $C$ to $CO_2$ is $\frac{14,580}{2\ 667} = 5467$ B.T.U.

Heat developed per lb. of oxygen for $C$ to $CO$ is $\frac{3281}{1\ 334} = 2460$ B.T.U.

of a compound, which must be broken up before its components can be separately oxidized. Thus, if both the sulphur and the iron in the compound FeS are to be oxidized, and it takes a certain amount of heat to dissociate the sulphur from the iron, it is only the difference between this amount of heat, and the sum of the heats developed by the oxidation of the separated components that can be utilized. All of the figures given in the table are derived from those given in Dr. J. W. Richards' Metallurgical Calculations, and are referred to the temperature of 15 deg. C. (59 deg. F.) and to normal pressure.

A glance at the tables will show that zinc sulphide compares very favorably with iron sulphide, as a metallurgical fuel, and makes a good showing when compared with partly burned carbon. It is scarcely worth while to spend time and labor in theorizing or in figuring on conditions, which must be imagined.

What is wanted are data, which can be determined only by experiment. It is seldom that the carbon in metallurgical operations is completely burned to carbon dioxide. This indicates the importance of analyzing the gases which escape from the furnace; for a deduction from the calorific value of the carbon must be made for any portion of it which escapes as carbon monoxide. Coal can be credited with only that amount of hydrogen which is not combined with oxygen; for it takes just as much heat to dissociate the water, as the hydrogen thus liberated will produce by burning.

Sulphide of iron is not a common constituent of ores. The bi-sulphide is the common mineral. The second atom of sulphur is distilled off before the smelting zone is reached. It is generally accepted that the sulphur thus freed is no aid to pyritic smelting. Even if it is burned to $SO_2$ in the furnace, the heat is given out where it is not needed. On the other hand this free sulphur is objectionable: (1) because its expulsion renders latent an unknown amount of heat; (2) because it requires an additional amount of oxygen and consequently of air, to be blown into the furnace.

To furnish 1 lb. of oxygen very nearly 4 1/3 lb. of air are required. An increased weight of issuing gases carries an increased amount of heat out of the furnace for the same temperature of escape. The consequent dilution also lowers the temperature at the focus of the furnace.

From the history of the introduction of pyritic smelting into the metallurgy of copper, it may be safely predicted, that, as a concentration process for the treatment of zinc ores it can only be introduced at some favored locality where a supply of suitable ores is assured; and even then it must await the arrival of the man and of the hour.

Lead sulphide, if present in considerable amount, will add some complications. But the bulk of galena can be removed by simple jigging before concentrating the zinc. If gold and silver are present, they will go mainly into the lead bullion or the matte. The small amounts which go off in the sublimed product can be recovered from the rich zinc sublimate. If no bullion or matte is produced, it will require an analysis of the slag to determine whether it will pay to add it to the charge of a lead furnace.

I have barely touched upon the problems which can be solved in the simple apparatus here shown. There are many other data, pertaining to pyritic smelting in general, which it is very desirable to have in hand.

Denver, Colo.

**The Kieselguhr Company of America**, Los Angeles, Cal., has issued an interesting booklet on "Sil-O-Cel, Nature's Non-Conductor," describing the uses of kieselguhr products. Sil-O-Cel is now finding application in the insulation of heat in electric furnaces and similar apparatus where the cost of fuel and power is an appreciable item of expense, but only a small part of which is actually consumed in the operation. Among the varied uses of Sil-O-Cel may be mentioned the heat insulation of all sorts of heating appliances, cold storage and refrigerating apparatus; the sound-proofing and fire-proofing of walls, floors and structures. Sil-O-Cel consists almost wholly of silica and is very light in weight.

## Rapid Method for the Determination of Chromium in Pig Iron, Cast Iron and Steel

BY H. E. WALTERS

Owing to the general tendency to add alloys or pig iron containing chromium to mixtures for iron castings, it has become necessary for foundries which control their product by chemical analysis to insist on the determination of the amount of this element in the scrap or pig iron used in the mixtures.

The methods given in the text books for the estimation of chromium require too much time for routine determinations and the writer felt that a method of his published some years ago (American Chemical Society Journal, Vol. XXVII, p. 1550 to 1553) could be modified so that a rapid and accurate determination could be made.

Experiment proved this to be the case and the method is used daily.

After working up the method, a search of the literature was made and it was found that a method practically identical was published by M. Phillips (*Stahl und Eisen*, Vol. XXVII, p. 1164 to 1167).

Credit for priority is, of course, due to Phillips, but as the journal used for the publication of his paper is consulted by but a few American chemists the writer feels that a description of the method will be welcome to chemists who are called upon to make this determination.

### Method

Weigh two grams of the sample into a No. 3 beaker, add 60 cc dilute sulphuric acid, cover with watch glass and heat until sample is in solution. Add 6 cc nitric acid 1.20 Sp. Gr. to oxidize the iron, and boil about two minutes. Filter into a No. 5 beaker and wash four or five times with hot water, the volume of the solution should then be about 125 cc.

Place over a light, add 5 cc silver nitrate solution and about five grams ammonium persulphate and heat to boiling, the manganese should be oxidized to permanganic acid and this may decompose into manganese dioxide. (If permanganic acid is not formed, more persulphate must be added as the formation of the permanganic acid insures the oxidation of the chromium). Boil about five minutes to destroy excess of persulphate, add 2 cc conc. hydrochloric acid and continue the boiling five to ten minutes to expel chlorine. Cool, dilute to about 400 cc with water, add a measured volume of a standard solution of ferrous ammonium sulphate to reduce the chromic acid, titrate the excess of ferrous iron with a standard potassium permanganate solution.

The number of cubic centimeters of the permanganate solution used subtracted from the number required for the volume of ferrous sulphate added, will give the volume of the permanganate solution equivalent to the chromium.

### Reagents and Remarks

*Sulphuric Acid*—A mixture of one part concentrated acid and five parts of water.

*Silver Nitrate.*—Four grams of the salt are dissolved in one liter of water.

*Ammonium Persulphate.*—The salt should be slightly moist.

*Permanganate Solution.*—The solution is made by dissolving 3.64 grams of pure potassium permanganate in water and diluting to one liter.

*Ferrous Sulphate Solution*—The solution is made by dissolving 45 grams ferrous ammonium sulphate in water, adding 50 cc conc. sulphuric acid and diluting to one liter.

It is unnecessary to have this solution exactly equal the permanganate solution, as a constant volume is used and the solution loses in strength. It is only necessary to find the volume of permanganate equivalent to the volume of ferrous sulphate used and this should be done every day.

25 cc of this solution will be ample for chromium up to 2 per cent when working on a two gram sample.

The permanganate solution may be standardized by finding the iron value, or by use of a pure chromium salt or sorensens sodium oxalate.

If the solution is standardized against iron the chromium value is found by the equation:

167.52:52.0 :: Iron valuue: $X$ equals chromium value.

If sodium oxalate is used the chromium value is obtained by the following calculations:

Weight of sodium oxalate $X$ .2587 equals weight of chromium. Weight of chromium divided by cc used for sodium oxalate equals value of 1 cc in terms of chromium.

In using the method on high silicon irons a few drops of hydrofluoric acid should be added while the sample is dissolving.

The method will be found very rapid for steels as no filtration is required.

I have encountered no difficulty on account of the presence of chlorides in making the titration with permanganate, and any chance of trouble from this source can be eliminated by adding the titrating mixture used in the determination of iron in the presence of hydrochloric acid.

## New Buildings for United States Bureau of Mines at Pittsburgh

Plans for the proposed $500,000 experiment station of the United States Bureau of Mines to be located in Pittsburgh, Pa., have been approved by the commission appointed by Congress for that purpose. The Federal Government now owns the property upon which will be erected a group of buildings, especially designed and adapted for the carrying on of the mine-safety work and other investigations in which the Bureau of Mines is interested.

The group consists of three main buildings, the central or mining building, having three stories, flanked by the mechanical and the chemical buildings. In the rear of these and inclosing a court will be the service building.

Between the main group and the power and fuel group will be the entrance to a series of mine shafts. One of these will be used as an elevator to carry heavy material and passengers from the lower level to the upper; another will be for tests of hoisting ropes and similar mining appliances; another will be an entrance to tunnels extending under the buildings and in which mining experiments, such as fighting mine fires, will be conducted.

Congress a year ago, in the public buildings bill, authorized a new home for the Bureau of Mines to cost $500,000. It is now expected that Congress in its present session will make a specific appropriation so that construction work may begin. It is hoped that contracts may be let by July 1. The director is hopeful that the buildings may be completed in the fall of 1915.

**Liquid Flow Recorders.**—The Yarnall-Waring Co., of Philadelphia, Pa., have just published a list of over 1000 users of the Lea V-Notch recording liquid meters.

# Blast Furnace Blowing Apparatus

BY J. E. JOHNSON, JR.

(Concluded from page 242, April issue.)

## Steam Valves and Their Settings

The conditions as to the steam valves for blowing engines are no different from what they are in any other type under similar conditions of size, speed, and economy desired. It is therefore obviously unnecessary and undesirable to go into an extensive discussion of this subject here.

In American practice the Corliss valve has won its way to almost exclusive use in high-grade steam engines. The poppet valves, which have given magnificent results in Europe, have never become popular in this country in spite of the economical results which have been obtained with them. It is probable that the conditions of operation are somewhat more exacting with that type of valve on account of its coming against a rigid seat, than they are with the Corliss valve with its rotating motion and absence of sudden stops. At all events the result is as stated, that the Corliss valve gear is preeminent in all the modern blowing engines in service and being built in America at this time.

The original Corliss valve gear was subject to the disadvantage that if the cut-off did not occur at a point somewhat before half stroke it did not occur at all, and steam followed full stroke with utter destruction of economy and terrific stresses on the engine.

With engines on constant mill loads, and particularly before the introduction of the compound which divided the expansion between two cylinders and greatly retarded the point of cut-off in each, this was generally not objectionable, but with the relatively late cut-off necessary for the compound engine, the variable loads to be met, and variations in the steam pressures owing to irregular conditions, so limited a cut-off was not satisfactory for blowing engines, so that for several years makers have been adding an eccentric which enables cut-off to take place under the control of the governor at any point up to about eight-tenths stroke in the high-pressure cylinder, and this constitutes a great advantage under operating conditions, so much so that no engine should be installed for furnace work without it.

Theoretically the low-pressure cylinder does not need the long range cut-off so much, but practically the necessity of operating even though steam pressure be down, and the low-pressure cylinder doing most of the work, makes it very desirable to have this gear on the low-pressure cylinder also, and personally I should not recommend any furnace man to buy a blowing engine not so equipped.

This feature is also of great advantage in starting an engine up from any position in which it may stop without barring it over, and in a heavy engine this is a convenience well worthy of the expense.

The resultant diagrams, Figs. 17, 18, 19 and 20,* indicate certain features as to the stresses in engines which are worthy of attention. It is proper to say that engineers are by no means unanimous on some of these points, and for that reason the views which I shall express are simply my own and are undoubtedly not in accordance with those of some others well qualified to pass on the subject.

There will be seen at the left of Fig. 8 a sharp point extending about 20 lb. per sq. in. below the line or zero pressure at the beginning of the stroke, which runs down to nothing at about 5 per cent of the stroke. This pressure comes from the re-expansion of the air left in the clearance space of the air cylinder, which, of course, is *in the same direction* as the pressure of the steam in the steam cylinder at that time. As soon as the pistons have moved a short distance this air re-expands down to atmospheric pressure, and thereafter the rising pressure in the other end of the air cylinder is increasingly opposed to the steam pressure. It will be seen that if the steam reached full pressure in the steam cylinder at the moment the stroke started, as is customary and proper in power engine practice, there would be practically double pressure on all the reciprocating parts and on the engine frame at this point, at which the velocity of the piston for a given amount of crank travel is very slow, so that this excessive pressure would come at a time to produce the least useful and the most frictional effect.

Inspection of the diagram, Fig. 3, will show that the engine builder has prevented this in part by delaying the admission of live steam so that it does not reach full pressure until after the piston has moved an appreciable distance, by which time the pressure of air in the clearance space is considerably diminished by re-expansion. For this reason the combined net pressure diagram of air and steam cylinders (Figs. 17 and 18) instead of showing a sharp "spike" on the left-hand end of the diagram, as it would if steam were admitted to full pressure at the beginning of the stroke, shows only a considerable "hump." The practice in the case of the low-pressure diagram of the same set (Fig. 5) is even better in this respect, for it will be seen that in this case the piston has traveled the whole distance necessary to permit complete re-expansion of the air before steam reaches full receiver pressure in the cylinder, and if a combined diagram were made for these cylinders the hump at the left, shown in Figs. 18, 19 and 20, would not appear.

Following through this same idea these builders eliminate any compression whatever, both in the high-pressure and low-pressure cylinders. In fact, there is nothing in either diagram to show that the steam first admitted at the beginning of the stroke may not blow through into the exhaust. It is not possible to say from the indicator diagram that it does so, and the care and good judgment of the builders make it unlikely, at the same time so considerable an economy of steam may be effected by very little compression, and with such a slight increase in pressure, that I consider a small amount of compression desirable both for the steam it saves and to make it absolutely certain that live steam does not blow through into the exhaust at the beginning of the stroke.

It will be noted that in this diagram (Fig. 5) and also to a less extent in Fig. 3, the exhaust of the steam is extremely slow. The exhaust valve does not open at all until the end of the stroke is reached, and the steam consequently has little time to leave the cylinder while the engine is turning the center. The result is the sharp "toe" at the exhaust end of the diagram, which in my judgment should come down as shown in dotted lines, very materially increasing the area of the diagram without any ill effect.

Turning now to the Southwark engine cards shown in Fig. 26 we see practice the exact opposite of that of the Tod company in these particulars. The compression pressure rises nearly half way to receiver pressure and admission is so early that full receiver pressure is reached at the very beginning of the stroke.

On the other hand, the exhaust is early, so that full vacuum is reached almost at the very beginning of the exhaust stroke, as it should.

If combined net pressure diagrams were made of this set of air and steam cards there would be found a "spike" of pressure at the beginning of each stroke which would just about double the total pressure on all the running gear and the engine frame for a brief instant of time at which it could deliver no useful work, owing to the low angle of the crank at that position, but in which it could greatly stress all the running gear and the frame of the engine itself and produce excessive wear if not an absolute hammering down of the brasses. Cases are on record in which certain engines of the walking-beam type broke their frames or pedestal caps repeatedly as long as the steam valves were set to give "lead"; that is, to give full pressure of steam at the beginning of the stroke, but which quieted down and ran without further difficulty when admission was delayed to compensate for the re-expansion in the air cylinders.

---

*See April issue for illustrations 1 to 27.

It will be seen, therefore, that the practice of the William Tod Company and of the Southwark Company is at the two opposite extremes in this respect. The Tod Company uses no compression and delayed admission, the Southwark uses heavy compression and early admission.

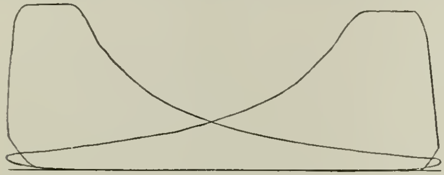

FIG. 28—STEAM CARD TAKEN FROM MESTA LONG CROSS-HEAD BLOWING ENGINE

I am able, through the kindness of the Mesta Machine Company of Pittsburgh, to present a pair of cards taken from one of their long cross-head blowing engines which seems to me to embrace the best practice in both respects. There is enough compression to reduce the total steam consumption appreciably, as can be judged by noting the percentage of the stroke still remaining to be made when compression begins; and then delays the admission sufficiently to allow full time for the re-expansion of the air in the clearance space.

In my judgment these cards are illustrative of the practice which should be followed by every blowing engine operator in setting the valves on his blowing engine. It will be noticed that the early closing of the exhaust valve has its complement in the sufficiently early opening of these valves to prevent any loss of area by failure of the steam to exhaust promptly.

In general it may be said that the blowing engine should be indicated at intervals of a few months to prevent or correct the multifarious misadjustments which can arise from many causes, many of which lead to bad economy and others to excessive stresses similar to those I have described and worse.

At plants where the economy of steam is not a prime consideration the hideousness of the steam practice which may prevail and still let the plant operate is beyond belief by those who have not seen it. There is probably no field about the plant where so small an investment of time and trouble will pay so great a return in steam economy and repair expenses avoided.

## The Turbo Blower

Within the last ten years the general introduction of the steam turbine and the high efficiency to which it has attained have brought about a great development in centrifugal machinery. It was formerly supposed that centrifugal fans were of no value for pressures above 1 lb. per square inch, and they were seldom or never compounded by putting two fans in series so as to increase the pressure they could attain. Instead, if a pressure of more than a few ounces was desired, the tendency was to pass to the use of the positive pressure blower.

The French engineer Rateau deserves the credit for working out into practical shape the use of the series fan capable of blowing pressures suitable for blast furnaces, and introduced several of these machines in Europe about eight or nine years ago.

Blast pressures in Europe are commonly not so high as those in this country, so these blowers were not suitable for American conditions. Moreover, it has been found to be universally the case that when a prime mover was introduced from Europe into America it had to be redesigned to meet American ideas and American conditions. This has been the case with the turbo blower. The first of these machines in this country was built by the General Electric Company for the Oxford furnace of the Empire Iron & Steel Company, and was started in 1910. A twin machine was started a few months later at the furnace of the Northern Iron Company at Port Henry, N. Y. Probably the largest single installation of these machines to date is that of the Iroquois Iron Company at Chicago, where the sole blowing power for two furnaces consists of three turbos with a capacity of 40,000 cu. ft. per minute each to a pressure of 30 lb.

More recently the Southwark Foundry & Machine Company has introduced the Rateau style of turbine into this country, and has already built several of them.

The Westinghouse Machine Company has as yet built no multistage turbine, but has built some single-stage machines for a pressure of 5 to 7 lb., these not being used in the iron industry, but under similar conditions in other industries.

The theory of the turbo blower is extremely simple. Air is admitted around the shaft, caught by the rapidly revolving vanes, or blades, of the fan, and has imparted to it a high velocity. This velocity is transformed into pressure, and the method by which this may best be done is a subject of some dispute among the designers of this class of machinery. The pressure obtainable in any one stage is limited by the speed which may be attained by the fan, and this is virtually the speed at which it is safe against the influence of centrifugal force.

The discharge from one fan is lead around through an annular port in the casing to the center of the next fan, which increases its pressure by a similar amount, and then to a third, and so on.

The number of stages to be used is not definitely settled. The Rateau blowers use eight, the first General Electric blower used six, but in the more recent types of construction the latter company have diminished the number of fans in series to three by increasing the speed.

The pressure increases more rapidly in the later stages than in the earlier ones because the density is increased by the increasing pressure.

The work put upon the air in compressing it heats it exactly as it does in a piston-blowing engine, but to a greater extent because the efficiency of the operation is lower with greater losses of energy in eddy currents, etc., which are eventually converted back into heat. The casings are therefore cored out hollow and cooled by water circulation to keep down the temperature of the air.

### THE SOUTHWARK TURBO BLOWER

The internal construction of the Rateau machine as built by the Southwark Company is shown in Fig. 29. The U-shaped discharge passages by which the air discharged from one fan is delivered into the central aperture of the next are clearly shown. In this turbine there are fans or impellers in two groups of four each, the inlet of the first group being next to the central bearing between the two sets. The air then progresses to the left and is discharged into a receiver pipe which carries it over into the inlet of the second group next to the inside bearing, and it then progresses outwardly through this group to the discharge at its right-hand end. In this way the end thrusts against the two sets of impellers are balanced against one another so as to throw as little work as possible on the thrust bearing.

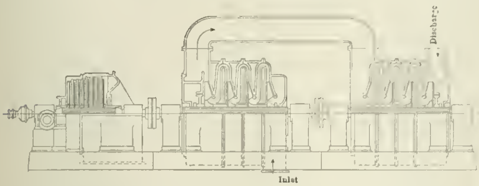

FIG. 29—SOUTHWARK RATEAU TURBO BLOWER

The turbine which drives the blower is shown in half section at the extreme left. The shafts for the turbine, and the two sections of the blower are all separate, and coupled together by flange couplings to permit an absolute alignment of each shaft in its own bearings. The shaft is located endwise by a thrust bearing at the left-hand end of the turbine shown in Fig. 30. This thrust bearing is capable of being moved and can be adjusted by a hand-wheel and screw to secure proper clearance and operation. The general arrangement of this machine is well shown by Figs. 31 and 32.

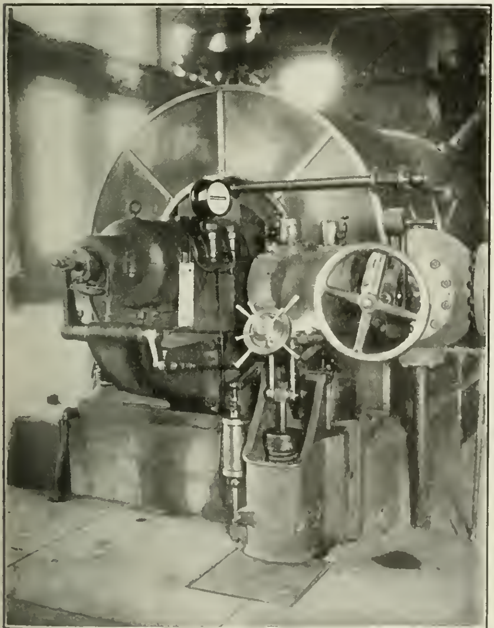

FIG. 30—STEAM END GOVERNING APPARATUS AND THRUST BEARING ADJUSTMENT, RATEAU TURBO BLOWER

The details of the design of the impeller, casings, etc., are highly technical matters in which mathematical theory and elaborate experimentation must go hand in hand to get the best results. To the great majority of users the only question of importance is how much steam is required to deliver a given quantity of blast at a certain pressure, and the details of the methods by which the guaranteed results are obtained is a matter of indifference to them and I make no attempt to treat of these matters, because it seems to me outside the field of the present work.

The turbo blower is of course entirely valveless, and it therefore escapes the troubles of valve design and operation which I have briefly described in connection with reciprocating engines. It is also entirely without anything comparable to the piston displacement of the reciprocating blowing engine. That is, it has no metering effect, and its speed is accordingly no gage whatever of the quantity of wind it is delivering under given conditions. It is the function of a blower or centrifugal pumping apparatus of any kind to produce pressure and the flow which results is proportional to the difference maintained between the pressure at the discharge of the apparatus and the pressure in the vessel into which it discharges. If a reciprocating blowing engine, running at a certain speed, delivered the desired amount of air to a furnace at say 15 lb. pressure, and if the resistance of the stock in the blast furnace suddenly fell so as to let the pressure drop down to 14 lb., it would make little or no difference in the quantity of wind delivered by the engine, but with the turbo blower it would make an enormous difference, because it would endeavor to maintain the same discharge pressure, and with the pressure difference between this and the resistance of the furnace increased by the drop in the latter, the flow would be greatly augmented. For this reason the turbo blower requires a governing device which shall control the quantity of air passing through it.

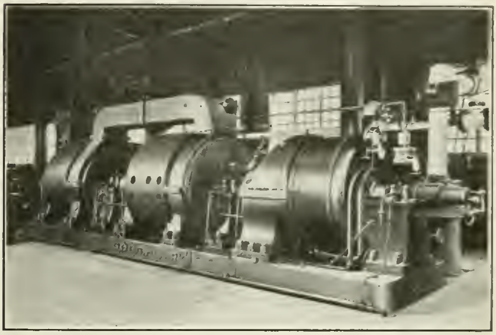

FIG. 31—SOUTHWARK RATEAU TURBO BLOWER

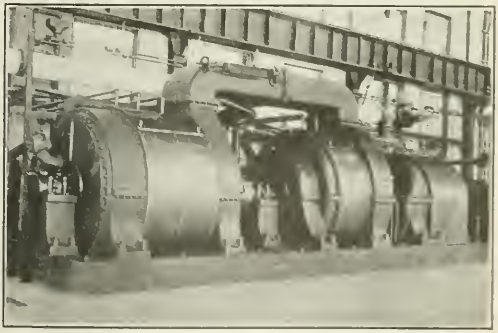

FIG. 32—SOUTHWARK RATEAU TURBO BLOWER

In the Rateau system the well-known principle of the

Venturi meter is used. In this an inlet pipe is provided which has a relatively small throat approached by a gradual taper and followed by an expanding taper to the normal diameter of the pipe. The difference in the velocity of the air at this throat and in the large area behind it, gives rise to a difference in pressure at these points which depends upon the velocity of the flow, and by measuring the pressure with a differential gage the flow can be accurately calculated and controlled. The arrangement is shown diagrammatically by Fig. 33. The partial vacuum at the throat of the Venturi meter is maintained constant by means of a relay working on the steam governor of the turbine. If the flow increases the vacuum in the throat of the Venturi tube increases, and this acting through the relay cylinder operates on the steam valve of the turbine and reduces its speed, which in turn reduces the difference in pressure maintained by the blower, until the quantity of air flowing through it is reduced to the amount desired. A centrifugal governor is interconnected with the same system so as to close the steam valve entirely in case of excessive speed.

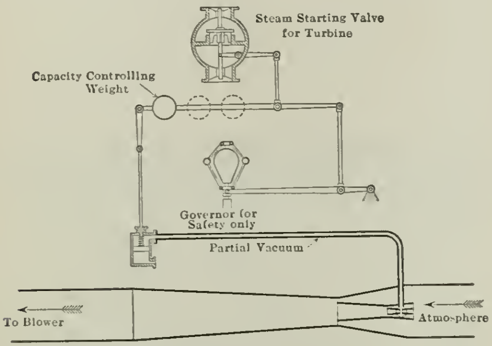

FIG. 33—METHOD OF CONTROLLING CAPACITY OF RATEAU TURBO BLOWERS—SOUTHWARK FOUNDRY & MACHINE COMPANY, PHILADELPHIA, PA.

### THE GENERAL ELECTRIC BLOWER

The principle of this blower is the same as that of the Rateau, but the number of impellers used is smaller, and the whole of the blower is built in one body, without the feature of balancing by having the flow from the two half sections of the impeller in opposite directions. This produces a shorter and more compact machine. This blower is shown by Figs. 34, 35, 36, 37 and 38, taken from a paper on the "Turbo Blower" presented by Mr. Richard H. Rice, of the General Electric Company, before the American Institute of Mining Engineers, and published in their Bulletin for May, 1914.

The governing device of this machine is on a somewhat different principle from that of the Rateau; it is shown by Fig. 34. The inlet pipe ends in a large inverted cone in which a circular diaphragm is suspended from a beam overhead. It is obvious that the area of the annular space between the diaphragm and the walls of the cone will vary with the location vertically of the diaphragm, and that the flow of the incoming air up past this diaphragm will have a tendency to lift the latter varying with the velocity of the air through the annular space, and the governing is done by the varying lift of this diaphragm. Thus while a different mechanism is used it produces about the same resultts as the Venturi tube.

If the pressure required by the furnace increases so as to decrease the flow of air under the speed at which the turbine is running, the diaphragm promptly drops down carrying with it the beam which operates on the steam valves, admits more steam and increases the speed of the turbine until the flow of air is restored to the normal. In this turbine also a centrifugal governor is provided to prevent excessive increase in speed.

The advantages of the turbo-blower are its small size, its entire freedom from reciprocating parts, and consequent ability to dispense with any but a light foundation, the small number of moving parts, *there being in effect but one,* and its ability to dispense with lubricating oil both in the steam and air ends. Great advantages are claimed for it also in the absolute steadiness of the blast which it produces, and the freedom from pulsation which results from a continuous discharge.

In the paper by Mr. Rice above mentioned he describes researches which prove the absence of such vibrations with the turbo blower, and their presence with reciprocating blowing engines, but whether this absence may be translated into dollars and cents of advantages in operation is a matter concerning which no proof has as yet been offered and concerning which I confess a considerable degree of skepticism.

It is claimed without hesitation that these blowers on account of the steadiness of their action, etc., enable a furnace to produce less flue dust and to make iron with less fuel than can be done with any other type of blowing machinery, but no definite data on this subject have been offered to support this contention, which also seems to me doubtful.

Fine points of this kind are always exceedingly difficult to prove in an operation of such magnitude as the blast furnace, and the situation is complicated by the fact that the turbines have in the nature of things, in many places at least, replaced obsolete blowing engine installed under bad conditions and therefore likely to be drawing steam into their inlet and discharging it into the furnace along with the air, with consequent detriment to fuel economy. Moreover, these engines being

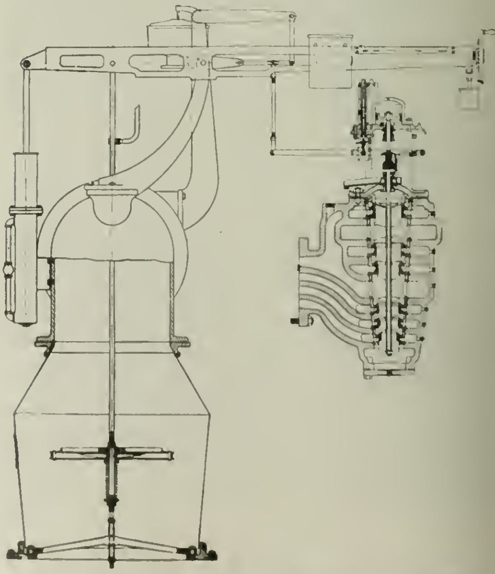

FIG. 34—CONSTANT VOLUME GOVERNOR FOR CENTRIFUGAL COMPRESSORS

old and uneconomical, and being presumably of the low-speed variety, they gave greater pulsation to the blast than more modern and higher speed engines. It is therefore extremely doubtful whether the mere fact that certain advantages are found where the turbo blower is used, which were not found before its introduction, is due solely to the type of blower introduced, or whether they would not have been obtained equally well with any other type of good modern blower.

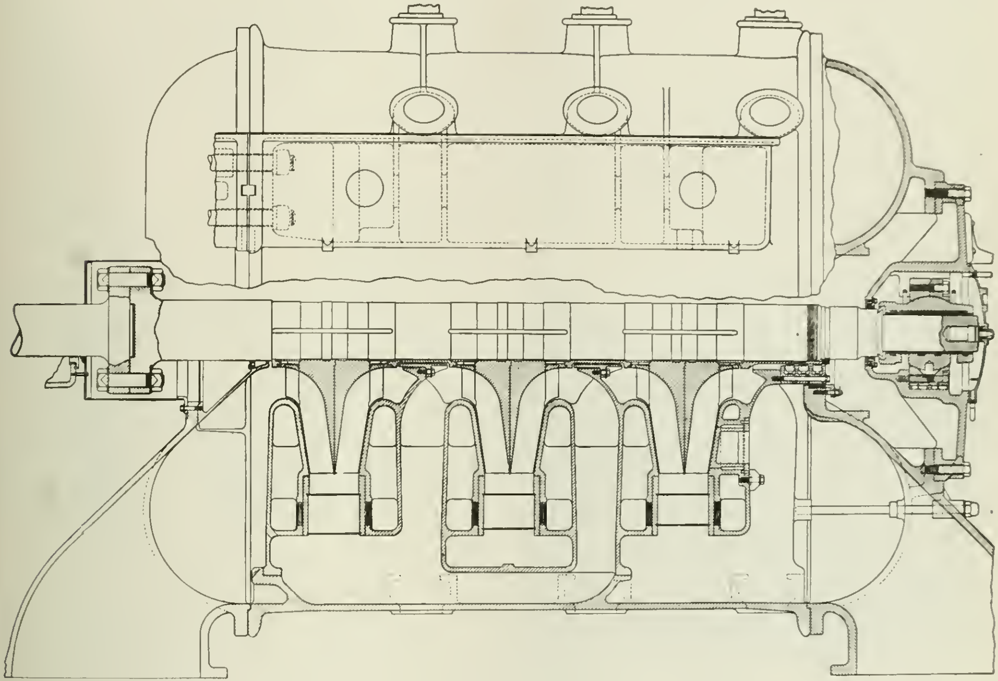

FIG. 35—THREE-STAGE GENERAL ELECTRIC TURBO BLOWER PARTLY IN SECTIONS

Much is claimed also for the accuracy of calibration of the air-measuring apparatus of these machines, and in a paper by Mr. S. G. Valentine, read at the February, 1914, meeting of the American Institute of Mining Engineers, and published in the *Transactions* for that year, he gives the results of his experience in the use of one of these blowers on a furnace which bear upon this point. Among other data he states that only 41 cu. ft. of air were required to burn a pound of coke based on the calibration of the air-measuring apparatus of the turbo blower. We shall subsequently see that about 63 ft. are required theoretically for this purpose without any loss by leakage, not only in the engine but around the stoves, the tuyere and elsewhere, and if only 41 ft. are used then one-third of all the fuel charged is being dissolved by direct deduction in the upper regions of the furnace and never reaches the tuyeres at all.

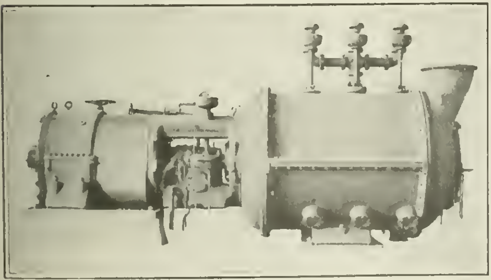

FIG. 36—CENTRIFUGAL COMPRESSOR RATED TYPE T—3—25,000—15/30—3000 3800 DRIVEN BY A 2000 3400 CONDENSING CURTIS STEAM TURBINE

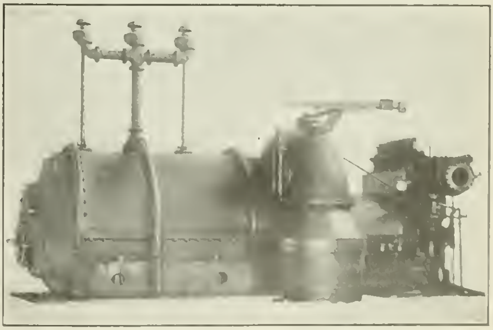

FIG. 37—TYPE T—3—35,000—15 30—2500 3250 F CENTRIFUGAL COMPRESSOR DIRECT CONNECTED TO 2900-H.P. CURTIS STEAM TURBINE

This hypothesis does not agree with the relative low fuel consumption reported by Mr. Valentine of about 2150 lb. of coke on an ore mixture consisting largely of magnetite which required a large amount of heat in the hearth, and, in fact, Mr. Valentine admits that his figures, based on the analysis of the top gases and carbon burned, differ from the calibration figures of the turbo blower by about 10 per cent.

I have information concerning practice in which the solution loss is likely to be much higher than it is in Mr. Valentine's practice, and in spite of this the actual quantity of wind per pound of coke figured from the analysis of the top gases and the actual coke burned at a number of furnaces for a long period of time was over 51 cu. ft., or more than 25 per cent in excess of that shown by Mr. Valentine's figures.

I have recently been advised by Prof. J. W. Richards, of Lehigh University, that he has gone over the data given by Mr. Valentine by two different methods and that both show clearly that the actual air delivered by this turbo blower must have been 15 per cent greater than the calibration of the machine indicated, and making this correction it would seem that the correct displacement of the turbo only corresponds to about 3 per cent more air delivered than the piston displacement of the antiquated engines it replaced. This is probably not altogether correct but it does seem to be established by these data that the calibration of this turbo is decidedly incorrect and that any claims made for superior economy based on these results are a structure on a foundation of sand which will not fare well at the hands of discriminating criticism.

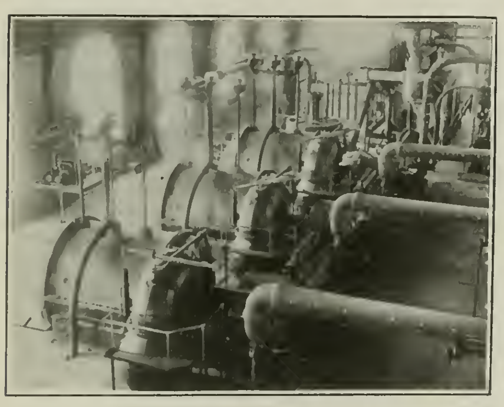

FIG. 38—THREE TYPE T—3—40,000—15/30—2500/3250 R.P.M. FAIR COMPRESSORS DRIVEN BY 2900/5200-H.P. CURTIS STEAM TURBINES INSTALLED AT IROQUOIS IRON COMPANY, CHICAGO, ILL., FOR BLOWING 500-TON BLAST FURNACES

Considering the extremely elusive nature of air and the possibility of error in measurements of its velocity, due to the fact that this velocity at points quite close together may vary very widely, I am led to the conclusion that the calibration of these machines is not yet on a basis of such complete reliability as their manufacturers seem to believe.

The subject as a whole is a new one, and the number of those who have had an opportunity to handle turbo blowers is very limited, the writer not being among the number. It is therefore not possible at this time to say the last word on this or many other details of this subject.

### The Disadvantages of the Turbo Blower

#### I. PULSATION OF DISCHARGE

Under certain conditions of operation at considerably less than the rated capacity of these machines, they are liable to a very disagreeable pulsation of the discharge, the theory of which I do not completely understand, though I believe it has been worked out mathematically. It seems to be due, however, to the fact that the volume is too small to maintain the delivery velocity necessary to overcome the pressure over the whole area of discharge, continuously, and the discharge therefore breaks and a backflow from the discharge pipe into the turbine casing takes place at short intervals, producing this pulsation. It is claimed to be overcome in the later types of these engines by the introduction of a butterfly throttle valve in the inlet pipe above the diaphragh.

#### II. INEFFICIENCY

The efficiency claimed for these machines by their builders under best conditions is 70 per cent, and of course this falls off on both sides of the maximum along the characteristic curve of practically all centrifugal pumping machinery.

The diagram factor of the air card from a well-designed blowing engine as a whole is about 95 per cent, and the mechanical efficiency of the engine as a whole, as I have previously stated, should be about 92 per cent. By diagram factor is meant the ratio of the actual diagram produced by a given engine under a given discharge of pressure to the theoretical indicator card with an adiabatic compression for the same pressure. The product of these two is about 87½ per cent, the difference between this and 70, or 25 per cent, is the handicap which the turbo blower must overcome to equal the performance of the reciprocating blowing engine.

Turbines have been brought to a very high state of perfection, particularly in very large units, such as are used in electric generating stations. But it may reasonably be doubted whether a turbine of, say, 3000 hp, with an efficiency of 70 per cent in the blower end, which would deliver 2100 air-hp, can do 25 per cent better in steam consumption than a steam engine properly designed and running with the conditions of boiler pressure, superheat, and vacuum, which are admittedly indispensable to the economy of the turbine.

If it be impossible for the turbine to do 25 per cent better than the reciprocating engine under these conditions than obviously the superior efficiency of the turbine will not offset the low efficiency of the blowing end, and the turbo blower as a whole will be a less economical unit than the reciprocating steam engine.

The steam expert of one large and extremely well-managed company has publicly expressed a doubt as to whether the turbo blower could get along with as little steam as the reciprocating engine, his company having both reciprocating engines and a turbo blower in the same building and operating under identically the same conditions.

#### III. FAILURES

There have been several wrecks of turbo blowers in this country, but these apparently have been due to defects in the design of new and larger units than had before been attempted, rather than to any inherent defect in the principles involved. This we have long since learned is the price which must be paid in the development of new equipment, and must therefore not militate unduly against the turbo. At the same time, it cannot be denied that turbines in other service have more than once "gone through themselves," to use the expressive phrase of the operator, with consequences so disastrous as to leave little of the structure of any value, even for repair purposes. Before the turbo blower can establish the supremacy towards which its builders are casting their eyes, it must establish a high degree of immunity from accidents, and also an economy not only eclipsing that of the best reciprocating steam engines, but rivaling that of the gas engine, which increasingly, as time goes on, must become a powerful competitor in blowing machinery.

### The Condenser

The auxiliaries of the steam plant at a blast furnace do not differ from those of any other steam plant of similar size and character, and for that reason it is not necessary to discuss most of them here, but the condenser is important enough to deserve some attention.

These for steam engines are of two types, the direct contact or jet condenser, and the surface condenser. Surface condensers are high in first cost and having an enormous number of packed joints are difficult of maintenance for continuous operation. Moreover, the water available at blast furnaces is not always of such character as to enable them to be kept as clean as they should be for best results, and when foul they soon lose their efficiency and the vacuum drops. For this reason when reciprocating blowing engines are used the elevated syphon condenser, working on the counter-current principle, and with positive means for removing the air, is very generally preferred.

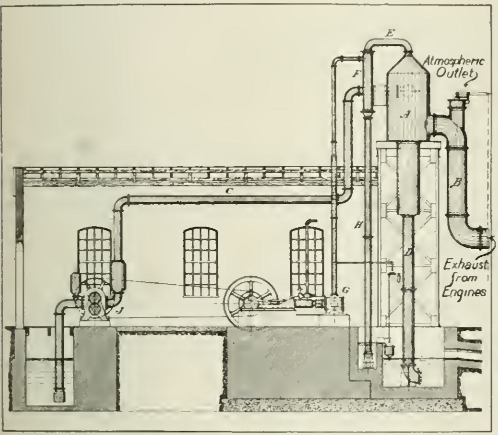

FIG. 39—WEISS CONDENSER

The first of these brought into use was the Weiss, introduced by the Southwark Machine Company, shown by Fig. 39. This is of the elevated type with a vertical tail pipe about 35 ft. long, long enough, in other words, to carry out the condensing water and water of condensation without pumping, against any vacuum which the condenser may produce. The air is taken off from the condenser by a dry-air pump, *G* in the illustration, the condenser being designed to discharge the air after it has received the maximum cooling possible, so as to make its density at this low pressure as high as possible and enable the air pump to handle it to the best advantage. The air pump engine drives by belt or gear drive a rotary pump, known as the Bibus pump, which supplies the water for the condenser. The Bibus pump is used on account of its high efficiency, but owing to its gearing, etc., this pump is not as well adapted to run submerged as is a plain centrifugal pump, and as condenser pumps in the nature of things are extremely likely to be submerged from time to time, I personally prefer the simpler if somewhat less efficient centrifugal machine which can run submerged indefinitely.

Several condensers of the same general style as the Weiss are now on the market, of which one of the best and most favorably known is the Helander, designed by Mr. A. H. Helander, formerly chief engineer of the Mesta Machine Company, now vice-president of the William Tod Company, of which a photograph is shown in Fig. 40. This condenser dispenses with the supporting tower used by the Weiss, the tail pipe of the condenser itself being made strong and stiff enough to support it. The air is taken off at the high point of the condenser body, as in the Weiss, different types of apparatus being used to pump it out.

In some installations a steam jet or modified exhauster has been used whose steam economy is not very much lower than that of a mechanical pump, and which is low in first cost, and completely eliminates moving parts. In other cases a crank and flywheel vacuum pump is used as in the Weiss. Water is generally supplied by a centrifugal pump driven either by a motor or by a small direct-connected steam turbine.

In blowing engine plants one condenser is generally installed for several engines, and this system has much to commend it, at the same time if steam for many units is to be condensed, the distance through which the exhaust has to be carried to the condenser becomes great and the piping large and expensive, while the vacuum realized on the further engine is probably never as good by an appreciable amount as in the nearer engines, so that this system must not be carried to extremes, especially as the high cost of the exhaust piping in a large installation would go far to pay for additional condensers. Neither must it be forgotten that several units of this kind have the advantage of greater flexibility and more freedom from general interruption than a single large unit.

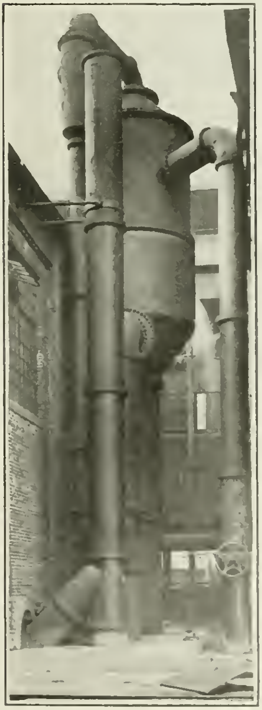

FIG. 40—MESTA HELANDER BAROMETRIC CONDENSER

For turbines the barometric condenser is sometimes used but to get the best results these machines require vacua which measured as absolute pressures are only from a half to a third of those used with steam engines, therefore it is highly desirable to have the exhaust connection extremely short and very large, so as to avoid both friction losses and leaks. For these reasons the condenser for the turbine is in the best practice placed immediately beneath it and in some cases forms the base upon which the turbine rests. For this service either some sort of jet condenser with water discharge as well as dry-air pumps, or a surface condenser is used. The latter is particularly desirable with turbines for the reason that their exhaust contains no oil and may be used for boiler feed without treatment, and for the high vacua desired in this service they have the advantage of not introducing any air dissolved in the condensing water, which is an important factor under these conditions.

As a result of these considerations new types of jet condensers have been invented and new designs of surface condensers brought out so that condensers as a whole have received a vast development in recent years. In relation to blowing power for furnaces, however, these conditions are not sufficiently important to justify more extensive treatment here.

### Combination of Turbine and Reciprocating Engine

There is an application of the turbo blower to blowing engines of which no actual installation has as yet been made, but the possibilities of which have been figured out on the basis of actual practice, and specifications prepared for such an installation. One is likely to be made before this work appears in print.

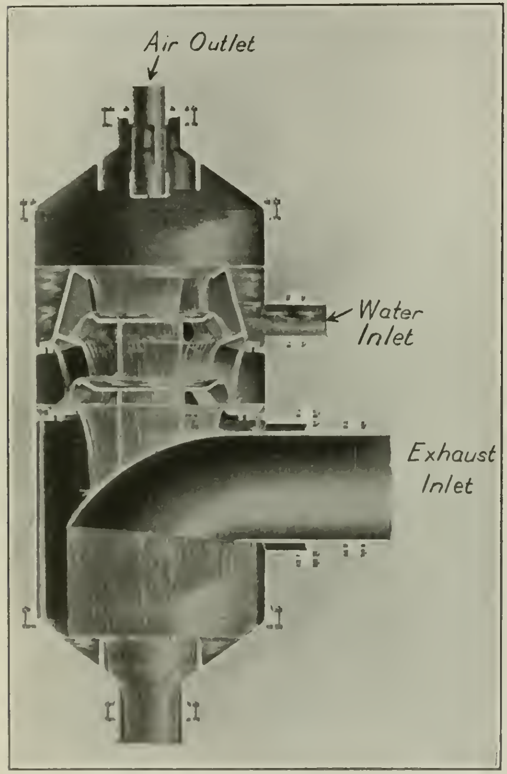

FIG. 41—VERTICAL CROSS-SECTION OF HELANDER CONDENSER VESSEL

This is a combination of the turbo blower driven by a low-pressure turbine, with existing blowing engines. The turbo blower is not designed to blow the full pressure required for the furnace, but only to do about one-half the work of compression, supplying the air under this partial pressure to the air cylinders on the existing blowing engines.

The advantage of this combination is that the turbine is a more efficient motor for pressures below atmospheric than the steam engine, particularly where high vacua are obtainable, and the turbo blower, while not more economical for low pressure than a good piston blower, is relatively more economical for low pressures of 6 or 7 lb. than it is for pressures of 15 lb. and upward, not because the turbo itself has a higher efficiency at the lower pressures, but because the friction of the large cylinders required for reciprocating blowers, unless they are most carefully designed, reduces the mechanical efficiency of that type of machine at low pressures, so that it is doubtful whether they are as economical below 6 lb. as are rotary blowers or perhaps turbo blowers, therefore the rotary unit as a whole is more economical for very low pressures than a reciprocating one. It is also much lower in first cost, and by combining the two types of machines and using each for the range of pressures for which it is best adapted, we obtain the highest efficiency with the lowest first cost. This is particularly true where existing installations are either uneconomical, unable to blow the pressure required, or unable to furnish the volume required.

By putting a turbine and condenser on the exhaust of a non-condensing engine we can recover a horsepower for about 30 to 35 lb. of steam, depending on the vacuum available. This power applied to a turbo will compress the quantity of air required to a pressure in ordinary cases of 5 to 7 lb. This increases the density of the air and therefore increases the capacity of the air cylinders of the reciprocating engines, and also obviously raises the pressure to which they can compress the air by at least the amount of this precompression.

The turbo blower will compress air to a pressure of $6\frac{1}{2}$ or 7 lb. in a single stage; therefore, in ordinary cases only a single-stage unit will be required in applications under this system.

Both the reciprocating engine and the turbo blower labor under certain disadvantages when used singly which are eliminated when they are used in combination, thus the turbo blower alone must have stages enough to blow the maximum power required, for instance, 30 lb., even though 15 only will be required 99 per cent of the time. Similarly the air cylinder of the reciprocating engine must be large enough for the maximum volume of air to be handled, even though this be required only occasionally. The turbo blower, on the other hand, can supply any increase in quantity of air desired within reason, without any change in its construction, while the blowing engine can compress to any pressure within reason without any change in its construction.

By combining these two units we obtain the volume capacity of the one and the pressure capacity of the other without the need of excessive size in one case, or multiple stages in the other. This arrangement has also the great advantage of retaining the metering effect of the piston of reciprocating engines, which is certainly more positive than the systems of volume governing so far applied to the turbo blower.

In the combined unit the question of governing the turbo practically takes care of itself, since the quantity of steam exhausted by the reciprocating engine controls the speed of the turbo, and this steam must depend upon the volume of air blown and the pressure to which it is raised. If the blast pressure required increases the tendency of the reciprocating engine is to slow down slightly and so slightly to decrease its discharge while the increased quantity of steam which it exhausts tends to increase the speed of the turbine and so to increase the pressure at which the turbo blower discharges, thus making up by an increase in density for any decrease in displacement of the reciprocating engine.

In the actual case for which specifications were prepared, there were three standard long cross-head blowing engines, two with good steam cylinders, the other with a poor steam cylinder, all non-condensing. The owners had obtained bids on a single low-pressure unit to take the exhaust from one of these engines and run condensing, letting one of the high-pressure engines run condensing with the other standing as a spare.

It was easy to show that on the basis of the guaranteed figures of the turbo blower manufacturers a single turbo blower could be installed which would supply the two good existing high-pressure engines with air compressed to 6½ lb., and this increase in density, with a slight and entirely permissible increase in speed, would have made the weight of air discharged by these engines the same as that now discharged by all three. The exhaust from both of these would have gone into the low-pressure turbine, and from that into the condenser, and would have been sufficient with any ordinary vacuum to drive the turbo blower at a speed which would enable it to supply precompressed air to both reciprocating engines. The third engine would have stood as a spare. The air cylinder heads of the blowing engines would have required to be closed in so that they could receive this air under pressure. A large inward-opening check was to be provided in the pipe carrying the precompressed air so that if anything happened to the turbo blower it could instantly be shut down and the reciprocating engines would then get their air supply from the atmosphere. This would have given the furnace two-thirds wind until the third engine could be started up, which would be only a matter of a few minutes. Finally it was shown that this equipment could be installed complete for a considerably smaller sum than would be required for the low-pressure unit, and that its steam consumption would be smaller than that on the other plan by several thousand pounds per hour.

This possible installation is set forth here because of the advantages which I believe it to have for such cases. It may also be said that the installation above described, while not installed as yet, was not rejected by the owners on account of any defect in the system, but only because they decided not to install additional blowing power at that time.

### The Gas-Driven Blowing Engine

It is now more than half a century ago that Otto first built internal combustion engines using the four-stroke cycle, and the economy of these engines was early recognized as being far superior to that of the steam engine in thermal units required. Before the days of the universal use of gasoline, gas was the only fuel used in such engines, and the difficulty of making suitable producer gas for them stood in the way of their earlier introduction.

In the case, however, of blowing engines for blast furnaces, which are in one sense only gigantic gas producers, the advantages of using the gas they supply directly in the engine cylinders are obvious. The first suggestion to carry out this plan was made in 1876 by Mr. Frank Firmstone, then manager of the Glendon Iron Works, to Mr. P. L. Weimer, of Lebanon, an engine builder of some note, but nothing was done in the way of carrying it out for nearly twenty years, when in 1895 Mr. B. H. Thwaites in England installed a small gas engine and operated it continuously for a considerable period on blast-furnace gas.

The idea was then taken up by German and Belgian engineers and to them is due the credit for overcoming the enormous technical, mechanical and financial difficulties involved in carying this simple scheme into successful practice.

It was only after engines of this type had reached a high state of development in Europe that they were introduced into this country, a circumstance which has caused much shame to some good Americans, but I believe does not reflect as much discredit upon this country as has frequently been claimed, on account of differences in conditions unnoticed by casual observers. These differences are financial and industrial rather than technical, and consist in the fact that in Europe capital can earn only a relatively small rate of interest and labor only a small rate of wages compared with what both command in this country, while raw materials are scarce and dear in Europe and have in the past been ridiculously cheap in this country, particularly coal.

The saving to be made must be bought, as we shall presently see, at the price of enormous expenditures in capital and in high-priced skilled labor, while its value could only be measured in terms of the saving in coal, one of our cheapest commodities.

When these technical savings were reduced by the amount of the high labor cost required to make them, the interest which the balance would pay on the capital involved was often less than could be earned by that capital in addition to the producing capacity of the plant otherwise.

It is true that this view of the subject involves the use of coal which might be saved for future generations by the other system, but this is a subject to follow which would take us far beyond the proper boundaries of this work and I shall not attempt to analyze it further than to suggest that, admitting the value of the "conservation" idea, it is proper to ask whether the saving of money, which represents value already created, may not be as justifiable as the saving of raw material which only has potential value.

Or to put the matter in different form, if the owner of a plant can make more interest on the capital invested by using more raw material than is theoretically necessary, who is to compensate him for the loss he makes by following the opposite course?

On the other hand, this policy is capable of great abuse, and Americans, as a nation, have had in the past and to some extent have even yet a tendency to prodigality and to ignore savings of various kinds which they might make, more through mental inertia than through any more worthy motive.

It may be admitted that the policy of conserving capital at the expense of raw material has often been carried too far, and the gas engine may be such a case. I shall give at the end of this chapter an outline of the method by which this question may be settled on its merits in each individual case.

The conditions to be met, and the difficulties to be overcome in making the gas-blowing engine a success may be briefly stated as follows:

First: Blast-furnace gas as it comes from the furnace contains a vast quantity of fine and exceedingly abrasive dust which must be completely removed before it is introduced in the cylinders of the engine or the latter will soon be destroyed by wear.

Second: The gas engine is a prime mover with little or no overload capacity, and with an efficiency which diminishes very rapidly as its load drops off. This is the opposite to the condition in the case of the steam engine, which has a very large overload capacity, and which maintains its economy well at loads very much smaller as well as much larger than its rated load. Therefore, when the blast pressure required by the furnace changes, the steam engine has no difficulty whatever in accommodating itself to the change, but the gas engine must either work at the disadvantage of an uneconomical light load normally, in order to be able to carry the heavier pressures when they arise, or else it must have special devices to enable it to compress less air when a high pressure is required, at the same time maintaining its speed and power.

Third: The gas engine when it began to be developed for use for blast-furnace gas was very largely a single-cylinder, single-acting engine, which, with the four-stroke cycle, meant that it received but one working stroke in two revolutions. The reason for this limitation was that it was considered almost impossible to operate piston rods with their accompanying glands at the high pressures and high temperatures involved in this type of engine.

Fourth: Owing to the intermittent and rather complex nature of their cycle these engines were in the early days freakish, unreliable, uncertain and difficult to operate to a degree which in the opinion of many American engineers debarred them from use.

Fifth: Owing to the operating difficulties just mentioned, and to the high repairs which went with them, the operating and maintenance cost was very high.

Sixth: The first cost of these engines, both for the engine proper, for foundation and for house, was and is even yet enormous, and as this first cost must be amortized at a relatively heavy rate on account of the rapid obsolescence, and somewhat rapid deterioration of these engines, the fixed charges on them were very high.

Coming now to the solution of these problems and difficulties, the result desired has been achieved in each case by the same formula. A vast amount of technical work of the highest order, the endurance of a vast number of operating difficulties which resulted in deficient blast supply for the furnaces at frequent intervals of uncertain duration, and made the managers regret the day that the gas engine was born, but which led eventually to methods whereby these difficulties might be avoided or overcome, an enormous number of experiments, many of which in the nature of things were unsuccessful, and the expenditure of great sums of money for development.

### THE CLEANING OF THE GAS

Great harm was done to the gas engine in its early days by the premature publication of the results of an experiment in trying gas which had not been thoroughly cleaned. It was claimed that only primary cleaning was necessary, and that the fine dust left by this simply went into the cylinder and came out again without doing any harm. A few months longer trial, however, soon showed that while most of the dust followed this course, enough of it adhered to the oily surfaces of the cylinder and piston rod to cause the rapid destruction of those parts, and it was then realized, once for all, that the gas must be cleaned, not only in primary washers, but must be scrubbed until the amount of dirt left in it was a negligible quantity. It is said that in present practice the gas passing into these cylinders is cleaner and more free of dust than the air we breathe.

This is not the place at which to deal with the question of gas cleaning, but it seems to be a fact that a positive and reliable solution of this problem, which could be guaranteed, was first obtained by the German engineer Theisen, and after the invention of his apparatus the development of gas-driven engines was much more rapid than before.

### ADAPTING THE ENGINE TO VARIABLE LOADS

In Germany the method has largely been adopted of holding open the inlet valve during a greater or less portion of the compression stroke, and so, in fact, cutting down the capacity of the air cylinder when higher pressures were required than those for which the engine was designed. But in this country this plan seems not to have found favor, and in general the gas cylinders have been made large enough to blow the maximum pressure normally required, any change from this being met by adjustment of quantity or quality of gas mixture and enduring the consequent loss of efficiency.

This is for the reason that when a furnace gets "tight" and the pressure goes up, it is frequently, if not generally an indication that it needs more air and if this be not supplied a scaffold is liable to form causing weeks or months of trouble.

Therefore the plan of reducing the volume of the blast in order to attain the increased pressure needed does not commend itself to furnace men; it is good for the engine, but likely to be very bad for the furnace.

### ADAPTING THE ENGINES TO RUN DOUBLE ACTING WITH TANDEM CYLINDERS

The difficulties which prevented this development in the early days were those which came from the intense heat acquired by any surface of small curvature, such as a piston rod, unless it was water-cooled. The head and barrel of gas-engine cylinders have been water-cooled since the very beginning, but on account of the mechanical difficulties the early engines were made single acting and their pistons were not so cooled but made long and allowed to get their cooling effect from the barrel of the cylinder and from the air in the crank chamber. This, with the plain flat piston heads without projections, enabled them to run without getting so hot as to cause premature explosions.

When it became necessary to obtain more working strokes per cycle the trunk piston was discarded and the regular piston and piston rods of the standard engine substituted, except that these were both made hollow and water-cooled by flexible or trombone connections to the cross-head or to the rear end of the piston rod. This having been brought into successful practice, the next step was to add a tandem cylinder and run the piston rod through to its piston, and with the experience based on the previous work this was soon brought into successful operation.

In the four-stroke cycle gas engine only one stroke of four is a working stroke instead of every one, as in the steam engine. Therefore by putting two double-acting cylinders tandem and having their working strokes alternate one with another two working strokes per revolution were obtained as in the steam engine. This resulted in an enormous reduction of the irregularities of power development and turning moment, from which the early gas engine suffered.

### ELIMINATION OF DIFFICULTIES AND UNCERTAINTIES OF OPERATION

This has been even more than the others a matter of patience and detailed attention to small and apparently unimportant points. The ignition system which was at one time under electrical control and with only one igniter per cylinder head, has now been made entirely mechanical with two or more independent igniters per cylinder end, so that one will ignite the charge if the other fails. Pilot lights on these igniters show whether they are working or not and enable difficulties to be cured before shut downs from the failure of both can occur.

The type of design which has the strength to resist the heavy internal pressures due to the gas explosion, and at the same time is so free from inequalities as to avoid heating strains, and the cracking and failing of cylinder heads and pistons which come from that cause, has gradually been evolved. The system for supplying water for cooling the pistons and piston rods has been developed so that the formation of air and steam pockets is prevented, and the overheating and premature explosion and cracking which arose from those causes are thereby avoided.

In this country the center crank construction has been discarded in favor of the over-hung single crank because the latter requires only one bearing, and definite knowledge of its adjustment and condition and of the stresses upon it are obtainable, whereas when the center crank is used, two main bearings are required, and the rocking stresses which may be developed by the maladjustment of one of them are enormous and entirely impossible to determine.

The valves of the engines have been put in convenient and accessible locations so that they can be readily removed for examination or replacement, and at the same time so that dirt will not lodge upon their seats, with the consequent destruction of the latter.

All of these details and many more have been subjected to the most rigid, patient, and penetrating investigation, so that the causes which led to these difficulties have either been avoided altogether or their results have been overcome to the best advantage.

### EXPENSE OF OPERATING AND MAINTENANCE

The thorough cleaning of the gas eliminated at one stroke a great number of the operating difficulties of the gas engine, while hand in hand with this went the knowledge obtained by both designers and operators from the patient investigation of and improvement of details described under the fourth heading so that great plants of gas engines may now be seen running apparently with but little more attention and no more repairs than would be required by an equal number of steam engines of similar power.

### THE REDUCTION OF THE GAS ENGINE TO STANDARD PRACTICE

The gradual elimination of the experimental work required in the early days of its development, and the fact that a number of reliable and experienced engine builders have undertaken its manufacture under competitive conditions, have all tended to reduce the first cost of these engines, while the standardization of designs and better adaptation of the means to the end sought have lowered their rate of obsolescence so that the amortization period is longer and this in conjunction with the lower first cost has greatly reduced the overhead charges.

## Type of Gas Engines

Owing to the length necessary on account of their tandem cylinders and to the excessive stresses to which they are liable from the nature of their working cycle, gas engines in large sizes for the iron and steel industries have never been built except as horizontals, therefore the number of types is very much more limited than is the case with steam blowing engines.

The first installation of gas blowing engines on a large scale in this country was that of the Lackawanna Steel Company at Buffalo, which was started about 1903-04, and has been the bone of many bitter arguments pro and con on the whole gas engine situation and on the particular type of engine installed. These are two-stroke cycle engines built under the Koerting patents.

They have a single double-acting cylinder on each side and every alternate stroke is a working stroke exactly as in the steam engine, their gas and air being supplied them by large pumps driven by cranks in the ends of the main shaft, one of which supplies the gas, the other the air, not only for combustion, but also for scavenging the cylinder of the burnt gases from the last stroke. This is done by a "plug" of air which is driven through the cylinder behind the burnt gases and in front of the fresh charge and to a great extent prevents the mixing of these, which would greatly reduce the efficiency.

No exhaust valve is used. The piston uncovers an annular port in the cylinder near the end of its stroke and the burnt gases and plug of scavenging air escape through this while it is uncovered. During the latter part of this interval the fresh charge is introduced into the rear end of the cylinder, but is prevented from escaping by the air plug.

This engine then avoids the necessity of having two cylinders to make each stroke a working stroke and avoids the exhaust valves of the four-stroke cycle, but does so at the price of two large crank-driven pumps which have to raise the charge to higher pressures to force it into the cylinder than is necessary in the four-stroke cycle in addition to which the air required for scavenging only, must be handled and compressed. These engines after more than ten years of continuous service are still in regular operation and, although steam-blowing engines are installed, they are held in reserve and the gas engines run by preference not only of the mechanical department, but also of the furnace manager, because they are not only more economical but require less attention and repairs than the steam engines.

The gas-cleaning installation at this plant is almost rudimentary as compared with more modern ones and the resulting gas much less clean, yet these engines are operating successfully with the original cylinders in some cases without even being bored out and lined with some of the original piston rods and almost all the original pistons.

These engines have horizontal gas cylinders and vertical air cylinders concerning which construction no more need be said than was said concerning the steam engine of that type, except that the high speed and great inertia of the reciprocating parts of the gas engine makes it even more unnecessary than in the steam engine, and it has not so far as I know been used in any other large installations of gas blowing engines in America.

Judged by the test of time and service this installation must be judged as great a success as an initial installation of any kind ever is. It was described in much detail by Mr. E. P. Coleman in Vol. XXXII of the *Transactions* of the American Society of Mechanical Engineers in which excellent article the statement is made that these engines require about 18,500 B.t.u. per indicated horse-power in the air cylinders, an efficiency of 13.7 per cent.

Recent types of four-cycle engines at three-quarter load give about 22 per cent efficiency at the shaft and reducing this by 10 per cent we get 20 per cent as the efficiency based on the indicated horse-power in the air cylinder or nearly one-half more than of the Koerting engines, so the reason for the exclusive use of the four-cycle type is not far to seek. At the same time these four-cycle engines represent a much more recent state of development than do the Lackawanna engines and it is claimed that the later examples of this Koerting type in Eprope give far better results than do the earlier ones. Still it must be acknowledged that while many attempts have been made to improve the economy of the two-cycle engines for all uses and in all sizes none of these attempts have ever succeeded in putting it in the same class for economy as the four-cycle, and it may now probably be said with safety that there are fundamental obstacles to success in this endeavor which will never be overcome.

Fig. 42 shows a gas blowing engine built by the William Tod Company with twin tandem gas cylinders on one side of the crankshaft and a blowing cylinder on the other side, driven by stretcher rods as described for the inside crank steam engine. This construction is no shorter than that of a straight tandem engine, and as the piston rods pass through the cylinder heads, and are supported by slides outside them in all cases, I do not fully understand the advantages of this construction, but it is in extensive use and seems to give good satisfaction.

Fig. 43 shows a similar design of engine built by the Allis-Chalmers Company, and Fig. 44 shows one of the largest installations of gas blowing engines in this country, also built by the Allis-Chalmers Company.

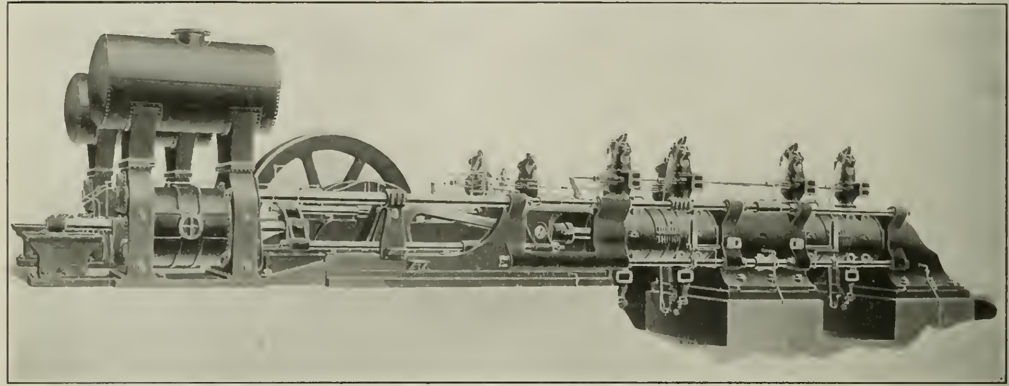

FIG. 42—42 AND 80 X 60 GAS BLOWING ENGINE

Fig. 45 shows in outline a straight tandem gas blowing engine built by the Mesta Machine Company with the crankshaft at one end and the blowing cylinder at the other, a design which I prefer to the inside crank type.

All these engines are of the four-stroke cycle, double-acting, double-tandem type with admission valves and exhaust valves all in the central vertical plane to give maximum accessibility without the necessity of removing cylinder heads and avoid the formation of pockets in the cylinder heads.

The details of the designs differ but not very much more than the details of steam engines.

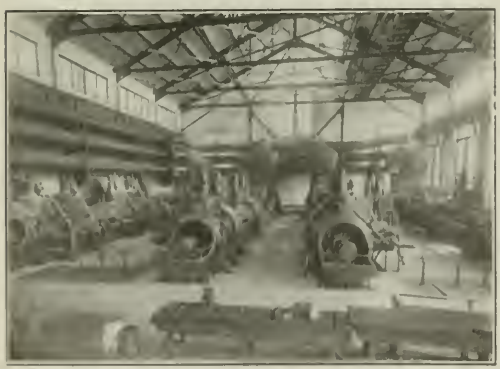

FIG. 43—ALLIS-CHALMERS 44 X 60 TWIN TANDEM GAS ENGINE WITH 60 X 60 AIR CYLINDERS

The air cylinders do not differ from those of steam engines except that the speeds at which they are required to run average higher and the valves must be designed to meet this condition.

### THE SPEEDS OF GAS ENGINES

It is a remarkable fact that a number of builders of blowing engines should balk at the idea of running a steam-driven blowing engine more than 40 revolutions, yet design and build regularly gas engines of the same stroke to run from 70 to 85 revolutions, and the situation is made the more remarkable by the fact that the reciprocating parts of the gas engine are about 50 per cent heavier than those of the steam blowing engine of similar capacity. This, with their high rotative speeds, double those of many steam engines, makes the inertia about six times as great as it is in the steam engine. The set of indicator cards from a gas-driven blowing engine, obtained through the kindness of the William Tod Company, of Youngstown, and shown by Figs. 46, 47 and 48, are from a 42 and 80 by 60 gas engine with a rated speed of 65 revolutions, with reciprocating parts weighing 94,500 lb. for each side.

From these I have prepared the net pressure diagrams for a pair of gas cylinders and the corresponding air cylinder, shown in Fig. 49. These have been reduced into a combined net pressure diagram of both sets of cylinders, shown in Fig. 50, on which is drawn the line of inertia effect at 65 revolutions and in dotted lines the inertia effect at 60 revolutions.

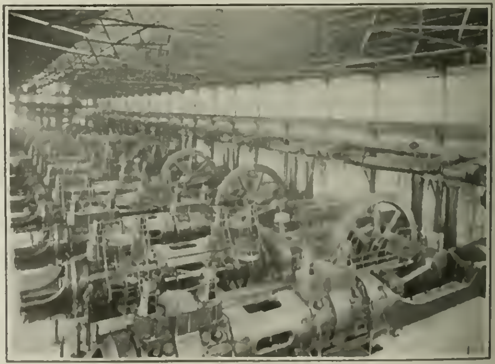

FIG. 44—ROW OF EIGHT ALLIS-CHALMERS GAS BLOWING ENGINES

In Fig. 51 is shown the resultant of these combined air, gas, and inertia diagrams at 65 revolutions. It will be seen that the equalization of power developed and power absorbed by this means is very good, but that the speed is, in this case, if anything a little too high, and that a better equalization would be obtained at 60 revolutions.

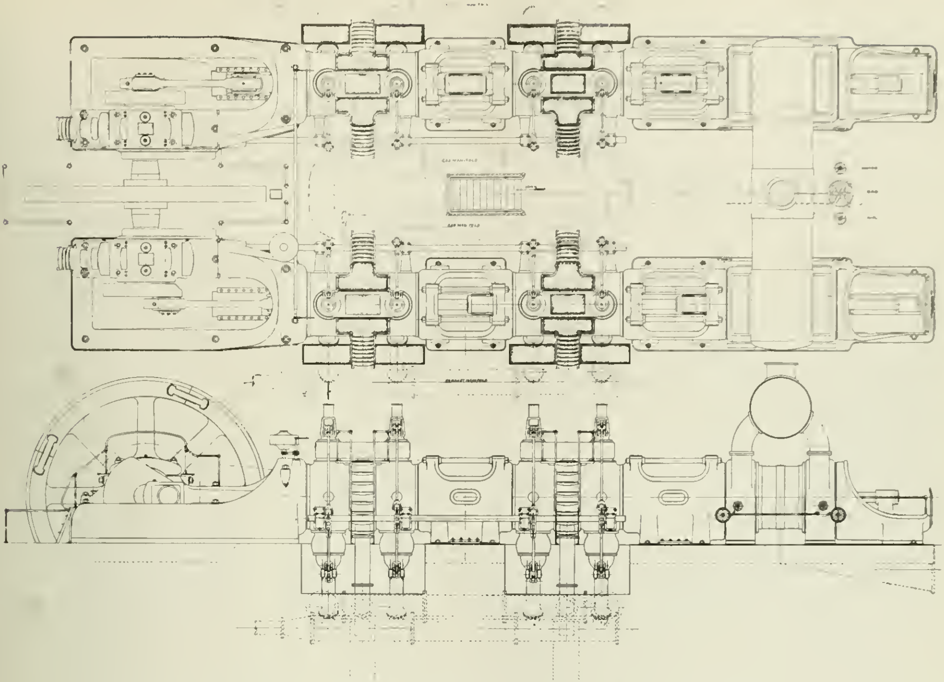

FIG. 45—MESTA GAS BLOWING ENGINE TWIN TANDEM ARRANGEMENTS

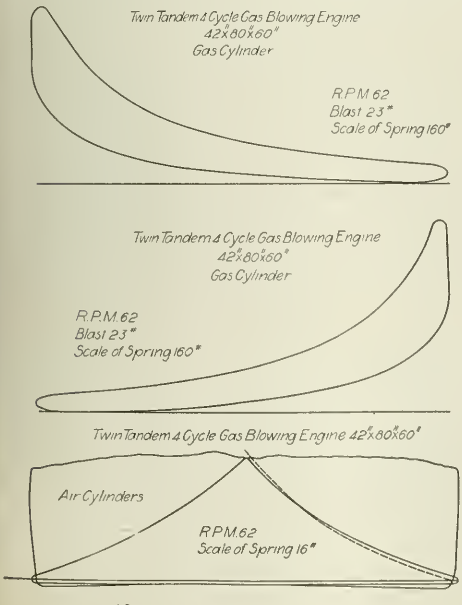
The stroke of this engine is 5 ft., that of the horizontal cross-compound, of which inertia and combined diagrams were presented earlier, was 6 ft., only 20 per cent more. It seems remarkable that this engine should be run at a speed of 65 revolutions, while the rated speed of the steam engine was only 40 revolutions, although it would obviously do better work if its detail proportions were right, at 55 revolutions, than it would at 40, with an increase in output of practically 40 per cent and without any countervail disadvantage.

I think the explanation is that the gas engine sim-



FIGS. 46 TO 48—TOD GAS ENGINE CARDS

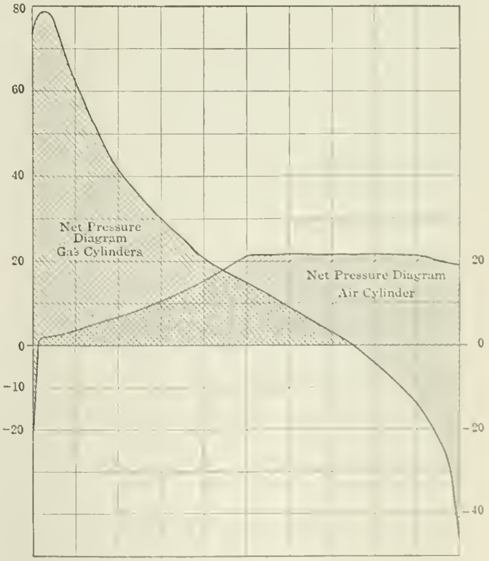


FIG. 49—NET PRESSURE DIAGRAM

ply will not run properly at low speeds on account of the frightful variations in pressure, and the reverses of stress consequent on them, and engine builders have been compelled to run them at a proper speed whether they would or not; while in the case of the steam engine the reversals of stress were so much less severe that the engine could endure them without the equalizing influence of the inertia effect and the obvious advantages of higher speed have been ignored because the engine could make out without them.

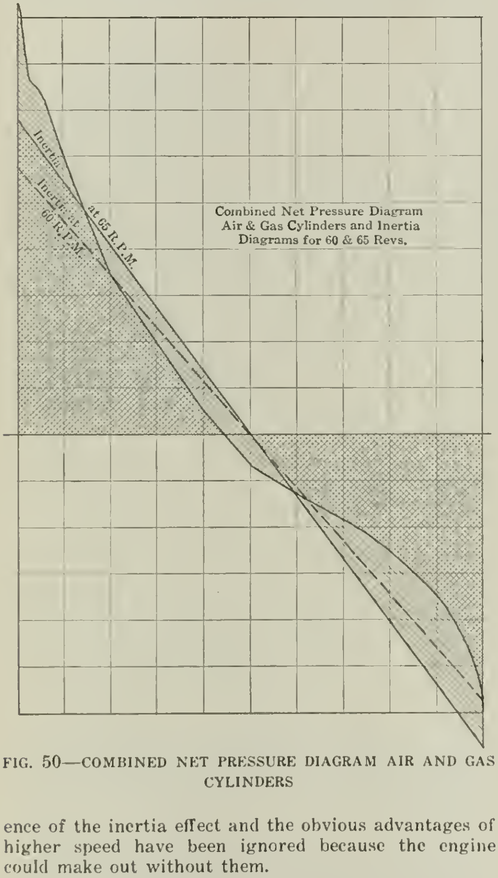

FIG. 50—COMBINED NET PRESSURE DIAGRAM AIR AND GAS CYLINDERS

It may be of interest to point out here also the "spike" of pressure due to the reëxpansion of the air in the clearance space which increases the total pressure on the running parts of the engine 15 or 20 per cent above what it should be at the beginning of the stroke.

FIG. 51—COMBINED DIAGRAM AIR, GAS AND INERTIA

It would seem that by delaying the ignition very slightly the explosion line of the diagram could be made to slope forward by a very small amount so as to offset the pressure from the reëxpansion of the clearance air and that this would not lessen the area of the diagram by an appreciable amount, while it would reduce the maximum stress on the whole engine to an important extent.

### The Choice of a Type of Blowing Engine

From what has been said it will be seen that we have the choice of three very separate and distinct types of blowing engines. It would be very desirable to make a definite pronouncement as to the superiority of one of these types, but it is not possible to do this for two reasons. First, the whole matter is in a state of active controversy at the present time, with the advantage shifting from side to side as one receives additional light upon one or another phase of the situation. Second, there is no definite solution for all cases because the conditions vary greatly.

At a steel plant which has within itself a vast market for power, the power producing capacity of the blast furnace gas must obviously be utilized to the fullest possible extent, so that the purchase of other fuel may be minimized or eliminated, and for this object an investment may be made of from four to eight times the annual net saving, depending upon the conditions and the judgment of the owner.

On the other hand a furnace set down in an isolated location with no other manufacturing or mining operation nearby to supply a market for its power is justified in putting in machinery only so good as will secure for its virtual immunity from the purchase of coal for power purposes, and will give the lowest operating cost exclusive of fuel.

Under these conditions it is obvious that no decision of this question for all cases is possible even if the actual physical data of operation available were complete, and were unanimously admitted by all parties in the controversy, which is by no means the case. The problem must be solved for each case on its own merits, and the lines of this solution may in a general way be laid down. It may be said in advance that recent investigation of this subject with details of actual capital and operating costs of gas engine plants by Messrs. H. J. Freyn, formerly of the Allis Chalmers Company; C. J. Bacon, of the Illinois Steel Company, and Arthur West, of the Bethlehem Steel Company, with data on the steam turbine and turbo blower, submitted by Mr. Richard H. Rice, of the General Electric Company, have indicated that the fuel cost of power production is by no means the only cost, and in many cases is not even the largest item, but that as we pass from the plain and simple types of machinery of old, to the more refined and economical but expensive types of to-day, the fixed charges due to investment rise at a rate which may equal or exceed that at which the value of the fuel saved falls. It is only by considering all these factors that we can arrive at the proper solution in any given case.

### The Outline of the Solution

The first question to be asked and answered is as to the value of power for purposes outside the blast furnace. If no market is at hand or can be created this is obviously zero. If on the other hand there is a market it is obvious that surplus power produced by the furnace must meet the competition of power produced by the cheapest means otherwise available. This will generally be determined in a broad way by the cost of coal at the given locality. Granting the existence of the market for the power at a price so determined, and knowing the quantity of gas to be produced by the given furnace plant we deduct from the former 40 per cent to represent the consumption of the hot blast stoves, and 5 per cent for other auxiliaries around the plant, the remaining 55 per cent is the gross amount which must supply the power required for blowing the furnace and that which is to be sold.

Fairly reliable figures are to be had as to the number of thermal units required per horse power, by each of the different types of prime movers. In the case of the gas engine this can be converted directly into cubic feet of gas required, based on the thermal units per cubic foot of the gas after it is cleaned and cooled and ready for the gas engine cylinders. But in the case of the steam engine and the steam turbine the efficiency of the boiler enters as a factor of much importance. It has been claimed that this may be put as high as 80 per cent, but the best and the most recent data concerning boilers and their operation with blast furnaces gas, indicate that they often reach in practice something less than 60 per cent. This also, however, is capable of investigation and determination for the detailed case in contemplation, and a figure corresponding to the results which may reasonably be expected, must be taken. Due allowance must be made for the steam pressure desired, and particularly for the degree of super-heat desired in the steam, and for the fact that the actual quantity of heat required in proportion to the theoretical is greater as the degree of super-heat rises.

With this information we may figure the number of cubic feet of gas required to produce a horse power in the case of the steam engine and the steam turbine, and in this case the thermal value of the gas per cubic foot in a partly cleaned and warm condition may be taken instead of that for its cold condition, which makes a difference of between 5 and 10 per cent in favor of the steam apparatus. This helps to offset the initial advantage of the gas engine that it only requires about two-thirds as many thermal units per brake-horsepower as do the steam driven motors.

We can now figure the quantity of gas needed to blow the furnace in each case and subtracting this from the total net heat available we obtain the amount available for the development of power to sell. From this we may determine the amount of such power we can produce in each case and its value, from which the operating cost of its production, exclusive of fuel, must be deducted. Against this we must set up the cost of the investment, the proper rate of amortization, and the proper rate of interest on the capital in each case. By comparing these with the net earnings for the power sold in each of the three cases, we can determine which is the best investment, always remembering that the amount of money available, or which can be raised, is more often than not strictly limited, and that the fact that a fine interest can be earned on an extra two or three millions is of little interest or value if the management cannot raise the extra two or three millions. It is also very necessary to remember that the type of motor determined upon as best to blow the furnace is not necessarily the best for developing power for sale. In fact in my judgment the probabilities are that the reverse is the case. The steam turbine owing to rotary motion, high steam economy, and ease of supervision has great advantages in driving electric generators, whereas for driving blowers it has no better means to apply to the purpose than the turbo blower whose efficiency is only 70 per cent as a maximum as compared with 85 per cent or more as the over-all efficiency of the piston blower. This gives the reciprocating engine, whether steam or gas driven, a long lead over the turbine for blowing purposes, while it has as outlined above many advantages over them in the generation of electric power.

For all these reasons it seems well to reiterate that each case presents a problem of its own which must be handled without prejudice by someone competent to weigh not only the technical considerations involved, but also that more serious and more difficult question which has wrecked so many engineers and their brilliant schemes: *How much interest will it pay on the capital invested?*

---

## Notes on Chemistry and Metallurgy in Great Britain

*(From Our Special Correspondent)*

### The Institution of Mining and Metallurgy

At the annual general meeting of this institution, on March 26, Dr. F. H. Hatch delivered his presidential address and took as his subject "The Relation of Geology to Mining." He said that originally the science of geology was founded to a considerable extent on the facts observed by miners; but at the present the situation has become reversed and mining is largely dependent on geology. There were many instances of successful mining operations resulting from the application of geological science: but the importance of geology in relation to mining was even greater than was generally recognized; and its due appreciation would involve either a more extensive training in geology on the part of the mining engineer or the cooperation of the mining geologist. With regard to modern views on the origin and formation of metalliferous ores, it was remarkable that British geologists, with very few exceptions, appeared to look on the questions of ore-deposits as a matter exterior to pure geological science.

It was announced that the number of members of the institution on December 31 last was 2,372, an increase of 114 during the year 1913.

### The British Westinghouse Company

The report for the year ended on December 31, 1913, shows that the position of the British Westinghouse Electric and Manufacturing Company has undergone a material improvement; and contains the satisfactory announcement of a 5 per cent dividend on the 15 per cent Preference Shares. The gross profit for the year is £223,103, out of which £44,100 for depreciation, £6,728 for redemption of Six Per Cent Prior Lien Debentures, £13,272 for interest on the Six Per Cent. Prior Lien Debentures, £49,645 for interest on Four Per Cent Mortgage Debentures, and £2,856 for expenses on surplus land and buildings are deducted; leaving £106,494 net profit. The dividend on the Preference Shares absorbs £50,000; £50,000 are carried to general reserve, and the balance of £6,494 is carried forward. The balance brought forward from 1912, amounting to £66,899 was devoted to the reduction of capital.

### FLAMELESS COMBUSTION

Professor **W. A. Bone**, in a recent lecture at the Royal Institution, described the principles and applications of the system of surface combustion devised and carried out at Leeds by himself and Mr. C. D. McCourt.

In its simplest form the apparatus for incandescent flameless combustion consists of a diaphragm of porous refractory material mounted in a suitable casing forming a chamber into which an explosive mixture of gas and air, in the proportions requisite for complete combustion, is admitted under slight pressure. Combustion goes on at and under the surface of the diaphragm, which becomes highly incandescent, without flame, and is limited to a depth of about 0.25

inch below the surface. Temperature is perfectly controlled by varying the rate of supply of the gaseous mixture, and the apparatus works efficiently in any desired position. The external air does not take any part in the combustion, and incandescence can be maintained in an atmosphere of carbon dioxide.

For furnace operations, heating crucibles and muffles, and annealing, the body or substance to be heated is surrounded by a bed or layer of refractory material enclosed in a suitable chamber and the gaseous mixture is injected into the poruos bed at a speed high enough to present back firing. A No. 39 Seger cone with a melting point of 1880 deg. C. has been melted in a crucible fired by a coalgas-air mixture; platinum can be melted without difficulty, and the temperature of a muffle can be maintained at 800 deg. to 1400 deg. C. with a gas consumption from 30 to 60 per cent less than that of an ordinary flame furnace of the same size. Satisfactory reports have been made on the working of some large annealing furnaces using Mond gas and town gas, and the melting of 50-lb. to 60-lb. charges of brass in tilting crucible furnaces has been effected with a consumption of only about 1.75 cu. ft. per pound of metal melted. The process admits of the use of any kind of gaseous or vaporized fuel of the requisite calorific value.

The great value of the invention in its application to steam boilers has been proved in practice. The heating tubes have an internal diameter of 3 in., and are packed with refractory material into which the gaseous mixture is forced through an inlet in the center of a plug of fire-clay, closing one end. Trials of a boiler so heated, at Skinningrove Iron Works in July, 1912, after five months' working, showed the utilization of 92.7 per cent of the net heat supplied, while 4.3 per cent was lost by radiation, etc., and 3 per cent in the products of combustion, but none at all in unburnt gas. A second installation has recently been made at the same works, and the firm of Krupps has been successfully using a boiler heated on the Bone-Court system since last October. Reports of the official steam trials of this boiler early in February confirm the results obtained at Skinningrove. The lecturer complained of this "purely all-British invention,"[1] having been described in the German technical journals as the "Bone-Schnabel" or "Schnabel-Bone" boiler instead of the "Bone-Court."

### Determination of Zinc in Bronze Coinage

Dr. T. K. Rose, assayer of the Royal Mint, read a paper before the London Section of the Society of Chemical Industry, in which he said that it had been decided to revive the old method of estimating zinc in coinage bronze which was abandoned about the year 1870. That old method had a great advantage in economizing the time occupied, and in fact, demanded only about five minutes personal attention for each estimation.

The method was very simple and was effected by heating one gramme of the alloy in a reducing atmosphere at a temperature of 1375 degrees for two hours and taking the weight of the residue. The details are as follows:

The one gramme sample is placed in a carbon crucible provided with a well-fitting lid, and from 8 to 16 of these crucibles are imbedded in charcoal in a graphite pot and subjected to the temperature named in an injector furnace. The composition of coinage bronze is copper 95 per cent., tin 4, and zinc 1. The loss after two hours' heating as described was found to amount to between 1.2 and 1.3 per cent., which was explained by the fact that whilst about 0.03 per cent. of the zinc was retained there was a large loss of copper, amounting to about 0.2 per cent.

With each batch of assays a sample from a trial plate of known composition was included, and the results, after correction, showed a variation of from 0 to 0.1 per cent., the average coming out at about 0.02 or 0.03 per cent.

Determinations have been carried out by this method, on alloys of zinc containing various amounts of that metal, up to as much as 90 per cent., and the results obtained were in very good agreement with those furnished by gravimetric and volumetric methods.

A noteworthy fact, however, was that as the percentage of zinc increased from 1 to 90 the copper loss during the heating grew to twice as great and rose to 0.4 per cent.

### Market Prices, March, 1914

*Tin* opened £174, and fell away to £172-£173, about which price it remained till the 17th, hardening to £174.5 on the 18th and to £175.5 on the 23rd, and touching £176.10 on the 24th, since easier and closes at £173.10.

*Copper* opened at £64, and declined gradually to £63.7.6 (13th), recovering to £64 on the 19th, and to £64.13.9 on the 23rd, and rising as high as £65.7.6 on the 24th; then eased slightly, closing at £64.17.6.

*Haematite* remains firm at 61/- and closes at the same price.

*Cleveland* opened at 50/6 and has remained close to this price; it was 50/4½ on the 13th and 50/9 on the 18th, since easing slightly, but closing at 50/9.

*Scotch Pig* opened 56/6 and has been either at or close to this price, closing, however, a little higher at 56/9.

*Lead* opened at £20 and was at first inclined upwards, being £21.10 on the 10th, and, after a drop of 2/6 on the 13th and 16th, it became rather quieter, closing £20.5.0.

*Differences*

| *Higher* | £ s. d. | *Lower* | £ s. d. |
|---|---|---|---|
| Copper ore, unit ..... | 4½ | Aluminium, ton ....... | 1. 0. 0 |
| Copper, ton ......... | 10. 6 | Caustic soda, ton....... | 5. 0 |
| Lead ............... | 5. 0 | Quicksilver, flask ...... | 10. 0 |
| Cleveland ........... | 3 | Sulphate of ammonia... | 6. 3 |
| Scotch pig .......... | 3 | Shellac, cwt. .......... | 2. 6 |
| | | Tin ore, ton............ | 6. 0. 0 |
| | | Tin, ton .............. | 2. 0. 0 |

| | £ s. d. |
|---|---|
| Aluminium, ingots, ton lots.......................... | 85. 0. 0 |
| Alum, lump, loose, per ton....................... | £5.5 to 5.10. 0 |
| Antimony, Star Regulus, per ton................. | £28 to 29. 0. 0 |
| Borax, British refined crystal, cwt................ | 17/6 to 18. 6 |
| Copper sulphate, per ton............................ | 22.10. 0 |
| Caustic soda, 70%, per ton.......................... | 10. 0. 0 |
| Copper ore, 10% to 25%, unit.................. | 10/10½ to 11. 4½ |
| Ebonite rod, lb. ....................................... | 4. 6 |
| Hydrochloric acid, cwt. .............................. | 5. 0 |
| India rubber, Para, fine, lb............................ | 3. 0 |
| Mica, in original cases, medium...................... | 3/6 to 6. 0 |
| Petroleum, Russian spot, gal.......................... | 9¼ |
| Quicksilver (Spanish), bottle.......................... | 7. 0. 0 |
| Sal ammoniac, cwt..................................... | £2 to 2. 2. 0 |
| Sulphate of ammonia, ton............................. | 12. 6. 3 |
| Sulphur, recovered, ton................................ | 5.10. 0 |
| Shellac, cwt. .............................................. | 3.11. 6 |
| Platinum, oz., nominal................................. | 9. 5. 0 |
| Tin ore, 70%, ton.................................. | £107 to 109. 0. 0 |
| Zinc, Vielle, Montagne.................................... | 25.12. 6 |

Steel castings direct from iron ore are now being made in the electric furnace by the Moffat-Irving Steel Works, Toronto, Canada, according to the *Canadian Engineer*. Average analysis of three heats is reported as C, 0.27 per cent; Mn, 0.74 per cent; Si, 0.27 per cent; S, 0.01 per cent; P, 0.031 per cent.

Electric furnaces of the Heroult type are used by the National Malleable Castings Company at the plant at Sharon, Pa., for the manufacture of electric steel castings for automobile and locomotive parts. A booklet issued by the company gives information regarding the advantages of electric steel castings.

# New York Convention of American Electrochemical Society

## Report of Proceedings, and Abstracts of Lectures and Papers Presented

The twenty-fifth general meeting of the American Electrochemical Society was held in New York City on Thursday, Friday and Saturday, April 16, 17 and 18. The attendance was excellent, there being more than 300 members and guests registered, and the meeting was a success in every respect.

The arrangements of the meeting were in the hands of the New York Section of the Society and the fullest credit must be given to the untiring efforts of its officers, Mr. Lawrence Addicks, chairman, and Mr. H. B. Coho, secretary and treasurer, as well as to the chairmen of the committees which had the different social functions and entertainments in their care. Mrs. L. H. Baekeland was the chairman of the Ladies' Committee, Mr. Lawrence Addicks was in charge of the steamer excursion on Friday, Mr. H. B. Coho of the smoker on Thursday night. Mr. Jacob Hasslacher, as chairman of the finance committee, made possible a lavish entertainment of the visitors. Mr. George C. Stone was in charge of the dinner-dance on Saturday night, Professor Arthur L. Walker was chairman of the reception committee, while the *Convention Daily*, published in three issues by courtesy of *Metallurgical and Chemical Engineering*, was in charge of Mr. J. Malcolm Muir, as chairman of the Publication Committee, and Mr. H. C. Parmelee as editor.

F. AUSTIN LIDBURY,
PRESIDENT AMERICAN ELECTROCHEMICAL SOCIETY

### Business Meeting

The annual business meeting of the Society was held at the beginning of the first technical session on Thursday morning at The Chemists' Club. President E. F. Roeber called the meeting to order at 9 a. m. and Mr. Lawrence Addicks, chairman of the New York Section, extended in a felicitous little speech the greeting of the New York members to the visitors.

Dr. J. W. Richards then presented the annual reports of the secretary and treasurer, which showed the Society to be in a flourishing condition. The number of members on Dec. 31, 1913, was 1376; it is now about 1400. The assets of the Society, invested in bonds, amount to over $6,000.

Dr. W. R. Whitney called the attention of the members of the Society to the organization of the International Electrical Congress, which will convene in San Francisco next fall. The American Electrochemical Society will hold its fall meeting of 1915 in connection with the Electrochemical and Electrometallurgical Section of this Congress.

The result of the annual election of officers was then announced as follows:

Mr. F. Austin Lidbury, works-manager of the Oldbury Electrochemical Company, Niagara Falls, N. Y., is the new president.

Mr. Pedro G. Salom and Dr. Joseph W. Richards were re-elected treasurer and secretary respectively.

Dr. Carl Hering, Dr. Wilder D. Bancroft and Dr. William Brady were elected vice-presidents; Mr. H. C. Parmelee, Dr. W. R. Whitney and Dr. Colin G. Fink, managers.

### Smoker

On the evening of Thursday the retiring president, Dr. E. F. Roeber, presented at The Chemists' Club his address on "Some Economic and Aesthetic Aspects of Electrochemistry." This is printed in full on page 344.

This was followed by a smoker which was very entertaining. The idea of the smoker was Election Night of Section Q. Mr. Coho, as chairman of the smoker, explained that at the last general meeting of the Society in Denver a certain wealthy mine owner was so impressed with the serious worth of Section Q that on his death he bequeathed to the section a complex-zinc-ore mine in Mexico. The question immediately arose, "What shall be done with the mine?" It was finally decided to hold an election to select a group of men and a process and work the mine. Three tickets had been in the field and the electioneering had been furious.

The Wet Party advocated a wet process for treating the ore. The Drys favored dry ore treatment, while a third party had arisen from the desire of the Bureau of Mines to run this mine and after an amalgamation with the I. W. W. advocated a fusion process.

Mr. Coho explained that the election returns were now coming in and that bulletins from various districts would be flashed on the screens. These bulletins were a source of much pleasure, being appropriately grotesque. Between bulletins the stereopticon operator flashed portraits of members of the electrochemical rougue's gallery, with verses setting forth their accomplishments in nursery rhymes. Then there were moving pictures, songs and presentations, mixed with the enjoyment of beer, pretzels and cigars.

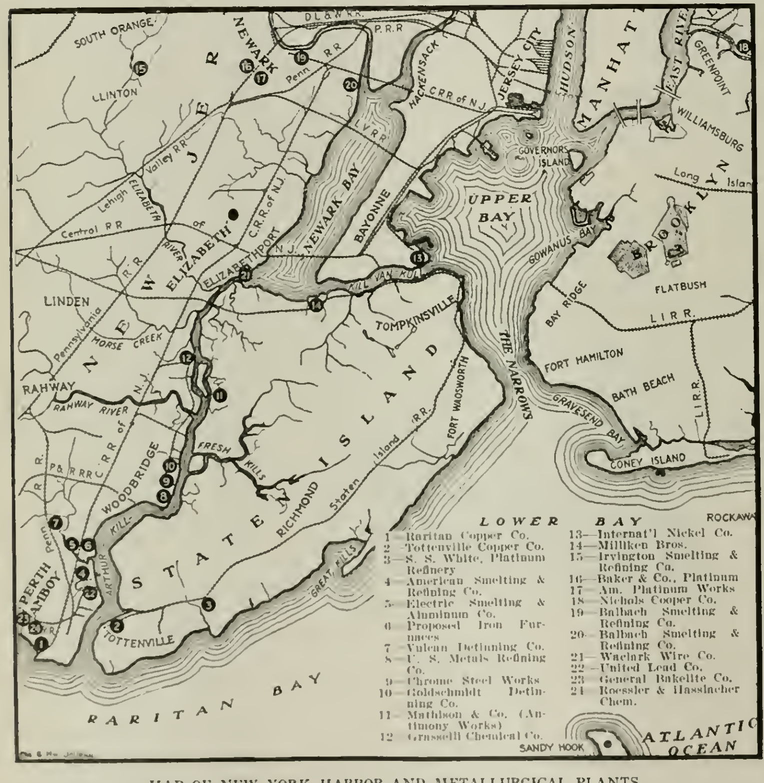
An election bulletin finally announced that the complete count of the ballots showed that the candidate of the Wets had received 6000 votes, the Fusion candidate 505, and the candidate of the Drys 2 votes, whereupon, in accordance with the new constitution of Section Q, the result was referred to the Council for final action.

In the meantime the candidate of the Wets, being apparently the successful candidate, was called on for a speech. He was interrupted, however, by the announcement that the Council had met and unanimously elected the Dry candidate president of Section Q and director of the zinc mine. Just here a wireless was received to the effect that the Fusion candidate protested agains the high-handed methods of the Council.

The fun was greatly enjoyed. About 11 o'clock a Dutch lunch was served and the members dispersed at a late hour.

### Boat Excursion on Friday

The boat excursion on Friday, in charge of Mr. Lawrence Addicks, had been equally carefully planned. The steamer *Isabel* had been hired to take the party down through New York Harbor to the Narrows and then around Staten Island to Perth Amboy.



MAP OF NEW YORK HARBOR AND METALLURGICAL PLANTS

The rain of Wednesday and Thursday threatened to spoil the excursion and there were many silent prayers for a change in the weather. When Friday morning came it was a beautiful day and nearly 200 members and guests with ladies participated in the steamer trip. The sights of New York Harbor were greatly enjoyed in the crisp spring morning. The entertainment on board included music and dancing, a luncheon and tea.

The works of the American Smelting and Refining Company at Perth Amboy and the adjoining plant of the United Lead Company were visited in the early afternoon and on the return trip the copper wire-drawing mill of the Waclark Wire Company in Elizabethport. A separate party went from Perth Amboy with Mr. Alfred H. Cowles to his plant in Sewaren, where his new alumina process is being tried out on a large scale.

The accompanying map shows the location of the plants visited; it is reproduced here from the *Convention Daily*. The map had been published originally in the *Engineering and Mining Journal*, but for the purpose of illustrating the boat trip the names of a few plants have been added. The map is interesting in illustrating New York City as a metallurgical center.

### Dinner Dance

The meeting was concluded by a dinner dance in The Chemists' Club on Saturday night, in charge of Mr. George C. Stone. The banquet was held in Rumford Hall. Mr. Lawrence Addicks was a very clever toastmaster. Speeches were made by the retiring and incoming presidents, Roeber and Lidbury, by Professor Bancroft, and by Mrs. L. H. Baekeland, whoe spoke beautifully of the proper sphere of influence of the modern woman. Dr. L. H. Baekeland then presented to the retiring president, Dr. Roeber, a beautiful silver loving cup "from his many friends."

Dancing followed in the social rooms of The Chemists' Club and was indulged in by a large party up to a late hour. Thus the twenty-fifth meeting of the American Electrochemical Society went into history.

### Ladies' Entertainment

Mrs. L. H. Baekeland was the genial chairman of the Ladies' Committee and a very fine programme of entertainment had been arranged, including a Thé Dansant at the McAlpin on Thursday afternoon, a theater party, in charge of Mrs. Maximilian Toch, on Thursday night ("Too Many Cooks"), a visit to the Morgan picture collection and an automobile party on Saturday morning, and a tea at the Plaza on Saturday afternoon.

### Technical Sessions

There were four technical sessions. Those of Thursday morning and afternoon were held in The Chemists' Club and those of Saturday morning and afternoon at Columbia University. All these sessions were opened by invitation lectures, followed by the reading and discussion of papers, of which printed advance copies were available. The attendance at all technical sessions was very good; it was never below 100, and often reached 200 present.

### Power Problems in Electrochemistry

The subject of the first technical session held on

Thursday morning in The Chemists' Club was a symposium of lectures and papers on power problems in electrochemistry, followed by a general discussion. The session was very well attended and lasted from 9:15 a. m. to 12.45 p. m.

### Characteristics of Electrical Energy as Affecting Chemical Industries

**Dr. Charles Proteus Steinmetz** presented a lecture on characteristics of electrical energy as affecting chemical industries. Industrial operations require materials, energy and labor. While the economical supply of energy is important for most industries, it is especially so for the chemical industries. In the chemical industries the cost of materials and energy predominates greatly over that of labor.

Energy is supplied to us by nature essentially in two forms, namely, the chemical energy of fuel, and the hydraulic energy of water powers. Considered merely as the raw material, as bulk source of energy, the chemical energy of fuel is very much cheaper. The lowest cost of energy of fuel as such is 0.01 cent per kw-hour, against 0.1 cent for electric energy from water powers. Hydroelectric energy can compete with the chemical energy of fuel only in those cases where there are compensating advantages.

CHARLES P. STEINMETZ

There are two such cases. First, where electrical energy can accomplish chemical results which cannot be accomplished by the chemical energy of fuel; such processes are reduction of aluminium, production of calcium carbide, and fixation of atmospheric nitrogen. Second, where the economic losses in efficiency and in cost of installation, and economic losses of making chemical energy of fuel available by converting it into the form in which it is used, are such as to make the cost of the energy required by the industry when derived from the chemical energy of fuel higher than the electrical energy derived from water power. The most typical illustration of this kind is the mechanical energy supply. While the chemical energy of fuel costs about one-tenth of what the electrical energy from the water power costs, when we convert the chemical energy of fuel into mechanical energy by steam plant, considering the interest on the investment and the inefficiency of the thermodynamic process as a whole, we find that almost always the cost of the mechanical energy derived from chemical energy of fuel is higher than when derived from the electrical energy transmitted from the water power, other things being equal.

One of the characteristics which makes electrical energy specially suitable for chemical industries is the possibility of concentration to an almost unlimited energy density, so that by electrical energy we can bring about chemical actions which cannot be brought about by the relatively low energy density available by combustion of fuel.

In electric furnaces we can reach temperatures very much higher than the highest temperature possible by the combustion of fuel, even with hot blasts and other auxiliaries. In those fields where a higher energy density is required electrical energy stands without a rival, irrespective of the cost, and the economy of energy supply merely determines the cost of selling and therefore the utility of the product in the industry.

A second characteristic of electrical energy is its control. We can control it very much more closely than the chemical energy of fuel in form of chemical combustion. We can produce electrical energy without contamination by foreign materials. Therefore, electrical energy finds application in chemical or other industrial processes, where a very close control of the energy is called for, and where the contamination by foreign materials, which is practically unavoidable when fuel is used as the source of energy, would be prohibitive.

Another characteristic of electrical energy is its ease and economy of transmission to great distances and its economical distribution, but its predominating advantage is the ease of its conversion into other forms of energy with a very high economic efficiency.

There is, however, one characteristic of electrical energy which is a very serious disadvantage, and that is that electrical energy cannot be economically stored, but must be consumed at the same rate at which it is produced. This makes the cost of electric energy dependent on the rate of its consumption, in the same manner as the cost of energy is dependent on the rate of its production. The cost of electrical energy generated in the same big power station may vary in a range of more than 1 to 200; that is, power may be sold economically and profitably at ½ cent, or less, per kw-hour at times of low load, while power generated during the hours of the peak of the load may cost the station more than $1 per kw-hour. In the analysis of the cost of electrical energy production proper consideration of the fixed charges of the plant is very important. This is particularly true of hydroelectric plants. The station load-factor dominates the cost of energy production.

To secure electrical energy at the lowest possible cost for chemical work it must be used at constant load and continuously day and night throughout the entire year, in other words, at unity load-factor at the consumers' premises.

In electric-furnace work a reactance may be used to intentionally limit the maximum demand. While this would lower the power-factor, this is of less importance in most cases than to exceed a certain maximum demand, because a poor power-factor can be corrected by synchronous condensers at relatively smaller cost than additional generating capacity can be secured to carry peak loads.

As most water powers are subject to limitation of output by low flow of water during certain times of the year, any industry that can afford to shut down entirely or at least partly for several weeks or even months during the drought can reduce the cost of its electrical energy supply. This means that conditions may require an annual shutdown, even with employees receiving full pay, and better net financial results may be obtained in this way than by absolutely continuous operation.

Another possibility of reducing the power cost is the possibility of sudden shutdown, from a minute or so to possibly several hours, on account of failure of transmission lines, because this eliminates the necessity of a steam reserve plant.

The very lowest rate for power can be obtained by those industries which can utilize intermittent and distinctively off-peak power in such a way as to fill the valleys in the station's load curve and bring the station load-factor nearly to unity. The rate for such a load should be considerably lower than for one taking continuous power throughout the year. If electrochemists can build up such a load, they will get the electric power at the very lowest rates.

### Power Transmission Economics

Mr. **P. W. Sothman**, of P. W. Sothman Co., consulting engineers, New York City, presented a paper entitled "Notes on Power Tranmission and Transmission Economics," with special reference to the economy of power transmission versus utilization in local electrochemical industries.

The author first discussed electric power generation from steam, waterfalls, gas producer plants and oil engines, and expressed the belief that the time would shortly arrive when power generated from gas and oil in competition with steam and water power would take a very prominent place in electrochemical work. He gave figures for the initial costs of power plants of the different types, including buildings, and for the cost of electricity per kw-hour on the busbars so developed, including all overhead and maintenance charges. These figures are given in Table I:

P. W. SOTHMAN

TABLE I.

| | Hydroelectric Plant | Steam Plant | Gas Producers | Diesel Plant |
|---|---|---|---|---|
| Initial cost per h.p. of capacity ......... | $125 | $100 | $100 | $100 |
| Power cost per kw.-hour .... | 3.6 mills | 6.25 mills | 4.95 mills | 5.62 mills |

These figures are based on a load factor of 60 per cent. and include fixed charges of 11 per cent. on the hydroelectric and steam stations and 12 per cent. on the gas producer and Diesel plants. The high load factors which are attainable in large electrochemical plants favor not only water power plants but also those operated by producer gas and oil, for the high efficiencies of the latter two are most marked when the load factor is good.

Table II. was published a couple of years ago and shows horsepower used per employee in a number of industries:

TABLE II.

| | Horsepower Used Per Employee |
|---|---|
| Tools and implements.................. | 0.678 h.p. |
| Cotton and woolen goods................ | 0.759 " |
| Miscellaneous manufacture............. | 2.35 " |
| Paper manufacture .................... | 13.33 " |
| Flour and feed........................ | 15.93 " |
| Lumber and woodworking............. | 6.76 " |
| Pulp grinding and excelsior............ | 23.00 " |

In electrochemical industries power forms one of the chief items of expense of operation.

In discussing transmission of electrical power Mr. Sothman mentioned that transmission at 10,000 volts was first attempted in 1891; in ten years' time the voltage climbed to 50,000, while before the end of 1909 lines at 110,000 volts were in operation. Now the mark has been set at 145,000 volts. The operator of electrochemical works should inquire whether this marked development in transmission cannot be taken advantage of by himself. But each case must be studied for itself.

How far is it possible to transmit energy electrically in usable quantities? Power in any amount may be easily transmitted on a straightaway line for a distance of at least 500 miles, and at that in a thoroughly reliable manner, though at the farther end of the line perhaps only 65 to 75 per cent. of the power may be received, even with the use of liberal-sized conductors.

At the present time there are no less than three long-distance lines in operation at approximately 145,000 volts, and the length of each is close to 240 miles. These are doubtless all well within the present economical distance limit.

In districts where a cheap coal supply is available, such as in certain parts of the East, it is not profitable to transmit power to greater distances than about 175 miles, even when competing with steam, for if the power is required in such quantities as to warrant the construction of a substantial transmission line, it would also warrant the building of a modernly equipped steam plant on the site of utilization which could supply energy at a cost as low as that of the transmitted power.

The use of a modern gas producer, burning coal costing $2 per ton, reduces the economical transmission distance of waterpower costing to generate four mills per kilowatt-hour to approximately one hundred miles.

Mr. Sothman next discussed the choice at voltage. The reason for using high voltage is to keep the conductor cost as low as possible. But with high-voltage lines there are other factors of expense which offset the saving in the size of conductors. Wooden-pole lines with low-priced pin-type insulators may be used for voltages up to 40,000 or 50,000. At 60,000 volts steel towers are almost universally used, the cost of which is higher. As the voltage further increases very expensive pin-type insulators or suspension-type insulators are used. At potentials upwards of 100,000 volts, the effects of corona become manifest. The critical voltage at which corona starts becomes lower with smaller-sized conductors.

In Mr. Sothman's opinion there should be no need of an intermediate voltage between 60,000 and 110,000 volts. The author discussed in some detail the great advances made in insulator design in recent years.

In conclusion Mr. Sothman gave some figures for the costs per mile of transmission line construction suited to different voltages. These are based upon the use of copper cables of No. 000 B. & S. gauge or their equivalent in aluminum. These figures are given in Table III. These costs do not include a telephone line or right-of-way. The wooden poles are assumed to be spaced 120 ft. apart and the steel towers 550 ft. apart. In the total cost of line 10 per cent. has been allowed for engineering and contingencies.

With proper care in the design and selection of materials, specially insulators, coupled with the use of suitable protection apparatus, a modern line should give practically uninterrupted service. But each particular case must be considered upon its own merits. For instance, an insulator may serve admirably on one line and fail utterly to give satisfaction on another line of the same voltage.

In conclusion Mr. Sothman called attention to the value of the peat deposits distributed all over the country. They may become more valuable for power supply than our waterpowers, especially as they are not liable to interruptions like waterpowers. A point

TABLE III.

| Description | Towers or Poles Inc. Footings | Cables and Erection | Insulators | Total |
|---|---|---|---|---|
| 12,000 volts. | | | | |
| Pole Line | | | | |
| Double circuit.. | $1,400 | $3,120 | $130 | $5,115 |

Copper based on 18c. per lb.

may be reached where the use of peat power plants in conjunction with water power plants may prove advantageous.

### Economies of Electric Furnace Operations

Mr. **F. A. Fitz Gerald**, of The Fitz Gerald Laboratories, Inc., Niagara Falls, N. Y., presented a paper on "Some Economies in the Use of Energy in Electric Furnaces."

"The relatively high cost of the heat unit generated by means of electricity as compared with fuel has led all those interested in the development of electrothermics to give serious consideration to economies in electric furnace practice. While the end sought is most desirable, it is unfortunate that its pursuit has led to much misdirected effort, which, instead of realizing economies, has resulted in waste and consequent retardation in electric furnace development.

"This is not surprising, since the same thing is observed in the pursuit of many other desirable objects, such for example as conservation, efficiency, eugenics, etc. No one will deny that these things are important, and no intelligent observer can fail to see the vast amount of misdirected and even harmful activity generated in relation to them. Perhaps the most striking analogy is found in certain activities for the relief of human ills. Recently there has been extraordinary agitation in favor of inducing the government to take up the mining and manufacture of radium.

"Leaving out all such secondary motives as the creation of bureaucratic jobs, personal advertising, etc., it is found that many people, otherwise intelligent, believe first that cheap radium is one of the most important things for the welfare of the human race, and second that governmental meddling will result in the production of radium at a low cost. Now, as regards the first belief, we do not yet know the extent to which radium is applicable as a curative agent, but, however important it may be, there is no doubt that its relative importance to human welfare in general is grossly exaggerated. As regards the second belief, even a superficial knowledge of the subject shows that while governmental meddling may mean selling radium at a lower *price*, its production will be at a greatly increased *cost*, since in all lines of activity outside its proper functions there is no more inefficient and expensive machine than a government.

"In electric furnace practice we have analogous error which is made in the name of economy; first in attaching an exaggerated importance to the saving of the heat units generated by the electric current, and second in the inefficient and expensive machinery used for the purpose, with the result that in slightly increasing the efficiency of the furnace there is a greatly increased loss of energy.

"In attempting to realize energy economies in electric furnace practice the first consideration should be the conditions governing the cost of power, and this can best be illustrated by abstracting parts of a typical power contract:

"1. The power company agrees to deliver so many horsepower 24 hours each day and every day in the year for a period of years.

"2. In case the purchaser's requirements are greater at times than the firm horse power agreed to be taken and paid for, the power company agrees to supply such intermittent demands, but in that case the amount to be paid for is the average of the highest daily one-minute peaks occurring during the month for which the charge is made.

"3. By "firm power" is meant the amount of power agreed to be taken and paid for by the purchaser *whether or not he uses it.* By "intermittent demand" is meant the highest one-minute peak occurring during any one day.

"4. The purchaser must when possible take current equally from the three phases, but whenever it is impossible and the difference between any two phases is greater than ten per cent. of the lesser he shall pay for power as though the current taken from each phase was equal to the greatest amount actually taken from any one phase.

"5. The purchaser must always maintain a power factor as near 100 per cent. as possible, but whenever this is less than 90 per cent. the average intermittent demand shall be considered as 90 per cent. of the maximum kilovolt-amperes taken for a period of one minute each day except that the average intermittent demand shall never be considered less than the firm horse power agreed to be taken and paid for.

"The trouble with many, indeed most, experimenters who are trying to start commercial plants, and even with some plants that are running commercially, is a failure to recognize the significance of the power contract. The important consideration in the plant, so far as energy economy is concerned, is that from the time the current is thrown on 100 *per cent of it must be used* 24 *hours each day and every day in the year.*

"Instead of this consideration being the first one, it is continually neglected in the pursuit of some fad such as increased efficiency in the use of heat units or saving some waste gases or working a complicated continuous instead of a simple discontinuous process. The result is that the exaggerated importance attached to these ends, desirable in themselves, leads to load factors far below 100 per cent. or to peaks involving expensive intermittent charges or to shutting down to repair or adjust complicated machinery built in the name of efficiency, while there is never any shutting down of the power company's bills.

"A general review of electric furnace work during past years shows that a great waste has resulted from the efforts of inventors working on smelting problems because they have attempted to develop elaborate schemes for preheating furnace charges, for utilizing CO gas, to obtain preliminary reduction, etc., before they have thoroughly worked out the simple furnace problems free from efficiency devices.

"The fundamental error of this work is the attempt to force too rapidly the natural evolution from the simple to the complex. Returning to our radium analogy, we have here another case of mistaken zeal in attaining an end desirable in itself, but relatively insignificant, so that much waste results from the use of cumbersome and inefficient machinery.

"Another wasteful notion dear to the inventor is the continuous process furnace. In many cases continuous furnaces are apt to mean complicated and expensive furnaces. One of those probably costs as much as several discontinuous furnaces. If an accident happens to one of the latter there is generally another ready to go on, but with the expensive continuous furnace there often is no spare one, or if there is it takes a long time to get it tuned up to normal working order, and meanwhile the power bill is eating up profits. The exaggerated importance attached to the continuous process has done harm in another way, for it has seriously retarded the development of processes for the utilization of off-peak power. This, obviously, requires discontinuous work, which has got a bad name, thanks to the efficiency idealist.

"Incidentally, it may be mentioned that a preliminary study of the off-peak problem is distinctly encouraging, but I do not believe that it will ever be worked out until it is taken up seriously by those having power to sell rather than by the consumer.

"After making sure that the consumption of power in a furnace plant will be continuous, the next step is to keep the power at 100 per cent. of that called for in the contract. In furnaces, of which that used for making silicon carbide may be taken as the type, there is after starting a rather gradual decrease in resistance, so in order to keep the power constant some means of regulating the voltage must be used. The cheapest way of doing this is to have a step by step method in connection with the transformers, but unless the steps are very close together it is not economical. A step by step device gives a load curve that looks like the teeth of a saw, and at the end of the year the energy wasted, represented by the spaces between the teeth, will pay for apparatus giving closer voltage regulation.

"In arc furnaces we have extremely sudden changes of resistance which should be taken care of by automatic regulators. These are very commonly looked on simply as labor-saving devices, but they are just as important as savers of energy. They avoid peaks, a fruitful source of expense, and keep the balance between the three phases. In a plant with which I am acquainted the installation of automatic regulation has increased the furnace yield somewhat over 10 per cent.

"As regards the question of power factor, this is not usually troublesome, except in the case of such an apparatus as the induction furnace. In this case much may be done by the use of a suitable condenser. Thus, very satisfactory results were obtained in the case of the American Electric Furnace Company's plant in Niagara Falls by the use of a synchronous motor with over-excited field coils. It was shown that in a plant of the kind running commercially the cost of the synchronous motor would be a good investment on account of the saving in the power bills.

"As a final useful suggestion in relation to energy economies I may mention that in some cases it is possible to provide a furnace or furnaces used to absorb any power which might otherwise be wasted for one cause or another."

## Power for Electric Furnace Work

A paper by **Mr. W. S. Horry**, of the Union Carbide Co., Niagara Falls, N. Y., on "Power for Electric Furnace Work" was read by title in the absence of the author, copies of the paper having been printed in advance. Mr. Horry pointed out that the electrochemical industries are rapidly outgrowing the available supply of electricity generated by the natural water powers of this country, so that in the near future they must inevitably be carried on with power generated from coal by some kind of prime mover. The extent to which the modern electric furnace requires energy is staggering. A single furnace some 16 ft. square will absorb 12,000 horse power. This amount of energy is sufficient for the light and power requirements of a small city, so it will be realized that all the available water power, great as it is, will not suffice for the needs of the electrochemical industry much longer.

It is fortunate that the production of electric power from coal has recently been simplified and cheapened. At present the cost of producing power by steam is low enough to be considered as rivaling the cost where water power is employed under the conditions that generally rule in the practice of electrochemistry.

The essentials for cheap power production from coal are close proximity to the coal mines, where plenty of water is available for condensing and where transportation facilities are adequate. The other requirements are met by the very nature of electrochemical processes. The load factor certainly will be 100 per cent and the power factor, which also enters into the costs, can be kept round 93 per cent at the switchboard even with the largest types of three-phase furnaces. Then, the first cost is kept down from the fact that it is not necessary to duplicate the generating machinery, modern boilers and turbines are quite reliable, and stoppages are remote and short and are such as not to constitute an objection for the purposes under review.

The actual prospective costs have been given by numerous contributors to other societies, such as Mr. H. M. Hobart, before the American Institute of Electrical Engineers. This author gives the investment cost as $35 per kilowatt for large powers generated at 60 cycles by steam turbine machinery and an operating cost of 0.25 cent per kilowatt hour as a minimum in cases where all conditions are favorable, and it is to be remarked that all conditions will at all times be favorable for such a plant in a properly chosen location, where electric furnaces constitute almost the entire load.

Mr. Horry thinks that Hobart's estimate is not too low or sanguine under the condition of operation of electrochemical industries. While the 25-cycle system is adequate for present requirements, the trend now seems to be to return to higher frequencies for general distribution. But large three-phase furnaces are not economically possible with a 60-cycle current. A scheme like the following may then be used:

The power of the three-phase, sixty-cycle furnace is limited. The cost of power is least when the power factor is unity. Therefore, good practice demands that this be kept high for the system as a whole and for the electric furnace in particular.

If we assume a power factor of 0.9, as measured on the high tension side of the transformers, and assume a delta voltage of 110, then the most power that a three-phase sixty-cycle furnace will take is about 2750 kilowatt, though by special design this figure can be somewhat improved. This is quite low. The modern smelting furnace is of decidedly greater capacity, to facilitate the extraction of its products.

But if this furnace be given six phases instead of three, it will take nearly double the power under the same conditions, while if twelve phases be chosen with twelve carbons in a ring at the furnace, then the power will be nearly four times that given, which would be sufficient for present requirements.

The six-phase secondary can be acquired by a mere change of the secondary connections from a three-phase transformer, and twelve phases can be similarly developed from two such transformers, one with its primaries connected delta and the other star fashion, the secondary voltages of the two being the same. Another function is then added to the transformers to increase the number of phases, as well as to lower the voltage, and, by this means, the even power produced from all dynamic machinery is reproduced within the furnace, although, for economical transmission, only three wires are employed in the line.

While the steam turbine seems at present the only device commercially available for 20,000-h.p. electric furnaces, it will not have the entire field to itself in the electrochemical industry. The gas engine is certainly the best prime mover in the steel industry, where blast-furnace gas is available in great quantities. The reciprocating steam turbine has likewise advanced.

The actual cost of electric power derivable from a modern steam plant is not, however, the only point of view for the electrochemist. He requires coal for preparing the materials for the electric furnaces. In electrothermal work it pays to roast the ore to be smelted and it pays to dry and prepare the coal used for reducing this ore. In other processes large amounts of coal are used to concentrate the solutions produced by electrolysis. Then it happens that a plant located where coal is cheap possesses advantages even if the cost of electric power from coal should be higher than that obtainable from a hydroelectric plant situated where coal is dear.

And finally there is always before the electrochemist the possibility of extracting the valuable constituents of the coal and of running the power plant with the residue. The byproduct coke oven produces sulphate of ammonia, tar, coke and gas. The two latter are of use to him in his process, and, if the two former can be profitably sold there would be a derived revenue that would operate to lower the cost of power. The scheme looks attractive for the reason that the byproducts can be extracted only to the extent that this is profitable, while the raw coal can be served to the boilers if its treatment before use is undesirable.

### Electric Furnace Regulators

**Mr. Robert Turnbull**, Welland, Ontario, Canada, then presented a paper on "The Thury Electric Furnace Regulator." The author discussed the advantages to be obtained from automatic regulation for the control of the current operating electric furnaces.

First, a great saving in wages, which for a three-phase furnace amounts to from 25 to 30 per cent. of the total labor employed on the furnace.

Second, a more efficient utilization of the current, resulting in maximum production, and shortening the time of the process.

Third, products of a higher and more uniform quality, owing to the steadier furnace conditions.

Fourth, the impossibility of mistakes, as the regulator always works in the proper direction and never without due reason.

The author then dealt in detail with the Thury regulator, pointing out its special advantages and describing its principle of operation. An account of this part of Mr. Turnbull's paper, together with illustrations, is reserved for our next issue.

### Power in Electrolytic Refineries

The following three papers were then read by title and called up for discussion, as they had already been read before the New York section of the Society:

"The Power Problem in an Electrolytic Copper Refinery." By **Lawrence Addicks.**

"The Power Problem in the Electrolytic Deposition of Metals." By **H. E. Longwell.**

"Sources of Direct Current for Electrochemical Processes." By **F. D. Newbury.**

An account of these three papers may be found in our issue of February, 1914, pages 91 to 94.

### General Discussion on Power Problems in Electrochemistry

A lively general discussion then followed.

Mr. Turnbull asked what would be a "reasonable" price for off-peak power in comparison with power used continuously 24 hours per day. There was no immediate reply from the many distinguished electrical engineers present, but, as will be seen below, Mr. Sothman gave later some interesting figures and still more characteristic advice later on.

Mr. Petinot spoke of the use of the Thury regulator and said its operation in connection with electric steel furnaces was as nearly perfect as could be desired. He had secured a regulation of load-factor as high as 97 or 98 per cent by the use of this regulator.

Mr. Lidbury thought that the different speakers had very naturally taken up the subject from their own points of view, and the papers showed that the point of view is an important factor in the consideration of any individual power problem. All speakers had shown, further, the great complications of their own particular phases of their power problem due to the very varied nature of electrochemical operations, in respect of size, the relative importance of power costs and the importance of other considerations that may enter into the problem. The horsepower used per employee varies in different electrochemical industries between 20 and 100 h.p. On account of this variety of conditions it is very dangerous to make generalizations without stating clearly the limiting condition. Mr. Lidbury finally said that there are enough electrochemical problems to solve, and operating engineers favor, above everything else, simplicity. He told the experience of an engineer in a concern where an elaborate "efficiency system" had been installed. When it had been in operation for a year and the efficiency expert called and asked how his efficiency system worked he was told it worked fine. "And how about business?" "Well, we have no time to attend to business now."

Mr. Hansen called attention to the fact that in general in arc furnaces, operating at low load, there is considerable wave distortion. As the load increases the wave distortion becomes less and less important.

Dr. Steinmetz said that wave distortion had been studied carefully 20 years ago in the case of the series arc-lighting system. The best advice that can be given on wave distortion in connection with electric furnaces is to get rid of it as soon as possible. The best means is reactance. If the power-factor is reduced by reactance we lower the wave-shape distortion and thereby eliminate the reduction of power-factor due to wave distortion. That means that where attempts are made to get as high power-factor as possible by cutting down all the reactance in the operation of the furnace the results have very often been disappointing. The mistake is made in most furnace operations to attempt to get a low reactance. Besides reducing wave distortion, reactances have the advantage that they prevent power fluctuations and balance the load on a three-phase system.

Mr. Lincoln, president-elect of the American Institute of Electrical Engineers, said that the calculation of the power-factor from the oscillograph record gives more correct results than a power-factor meter. If the current wave is of the same shape as the voltage wave, the power-factor meter gives the true power-factor, but if the current wave and the voltage wave are not of the same shape the power-factor meter does not give the true power-factor, and the latter must be determined in some other way. Wherever an arc is present, the current wave is not the same as the voltage wave. Mr. Lincoln thought that Hobart's figures for the cost of power from steam related to ideal conditions and could hardly be realized in practice.

Mr. Hansen explained that he had determined the power factor from oscillographic records and gave a very interesting account of the trouble experienced when the basic slag of an electric furnace evaporates and reacts with the silica roof.

Mr. Sothman thought it was agreed that the question of power is one of the most important in the electrochemical industry. In replying to Mr. Turnbull's former question he said he knew of Canadian contracts for power where the fundamental rate was $28.50 for power 24 hours a day for 365 days a year. If the consumer would permit shutting off 20 per cent of the power during the four winter months in the year for one and one-half hours per day that power could be had for $24, which is a reduction on the total power bill of about 22 per cent. In other cases reduction as high as 34 per cent had been made if it was off-peak power. If the amount of power per employee is relatively very large it pays to buy off-peak power. If there are ten men working on a certain process and 1000 horsepower is being used and off-peak power can be purchased 25 per cent cheaper it is more economical to buy the off-peak power, and lay the men off for an hour or two, provided the process is not in any way interfered with as to the final results. But in speaking of the cost of power it is very important to state clearly how the power is measured and where it is measured, and to look for the small gifts or no-gifts mentioned in the power contract. "Gentlemen, when you are about to sign a power contract open your eyes—open your eyes twice."

Dr. Hering, in commenting on Dr. Steinmetz's paper as eminently fair and clear, recommended it to the perusal of the power engineers, who seemed to be very slow to understand that it is to their interest to sell valley power quite cheaply.

### Policy of the Bureau of Mines

As the last subject of the Thursday morning session a letter by the Director of the Bureau of Mines, **Dr. J. A. Holmes**, dated April 15 and addressed to the President of the American Electrochemical Society, Dr. E. F. Roeber, was read by the Secretary, Dr. J. W. Richards. It is exceedingly interesting in defining the policy of the Bureau. Dr. Holmes' letter reads as follows:

"I regret exceedingly to find that important administrative matters in connection with the mine safety work of the Bureau will make it impossible for me to attend the meeting of the Electrochemical Society in New York tomorrow as I had intended doing; and also that these matters will prevent my being with the members of the Society during the steamer excursion Friday.

"I regret not being able to attend this meeting of the Society all the more for the reason that I anticipate a few of its members may have been misled by recent press dispatches as to the nature and extent of some of the Bureau's proposed work, especially in relation to the radium industry, and I might have been able to say something to correct misapprehensions along this line.

"In connection with the subjects which the Bureau is authorized to investigate it acts for the Government of the United States in the same way that any engineer or chemist may act for a private corporation by which he may be employed.

"Thus, for example, in relation to the radium industry, about which the press has of late had a good deal to say, the Government needs for use and especially for researches in its hospitals located in different parts of the country under the Public Health Service and under the Army and Navy, a certain quantity of radium, which at the prevailing market price will cost between $3,000,000 and $4,000,000. The chemists and mining engineers of the Bureau of Mines in a study of the radium-bearing ores on the public lands with a view to efficient development and the prevention of unnecessary waste, have developed methods of concentration and treatment through the use of which they estimate that the radium needed by the Government can be produced from ores now belonging to the Government at a cost considerably less than half of the existing market price. Other parties have discussed the subject and have framed legislation with a view to enlarging the scope of these operations; but the accredited representatives of the Bureau of Mines have neither planned or advised the extension of this work beyond the Government's own needs.

"Under somewhat similar circumstances a few years ago the Government was unable to purchase at what was considered a reasonable price cement for the construction of the Roosevelt Dam under the Reclamation Service. Under the circumstances a cement plant was erected on the ground, and an adequate supply of cement was manufactured and the dam constructed by the Government at a cost of nearly $1,000,000 less than the original bids by private parties. Nevertheless, no one recommends or expects the Government to go into the general cement manufacturing business.

"Insofar as its general work is concerned the policy and purpose of the Bureau of Mines is to help, and certainly not in any way to hinder, the professional work of private experts or the operations of private persons or corporations. Our work relates primarily to the public welfare, especially with relation to safeguarding the lives of employees, the prevention of unnecessary waste of resources, and the general advancement of the mining, metallurgical and other mineral industries. It is in the performance of this general public duty and in the carrying out of this general public purpose that I should be glad to have, and I feel sure the Bureau of Mines will receive, the hearty co-operation of the members of the Electrochemical Society."

A complimentary luncheon was served at 1 o'clock.

### Electrolytic Flames

After lunch had been taken in the social rooms of The Chemists' Club, the afternoon session began sharply at 2 o'clock with a most interesting experimental lecture by Professor **Wilder D. Bancroft**, of Cornell University, on electrolytic flames.

He called attention to the fact that metals do not give the same flame color for all of their salts. For example, sodium salts usually give a spectrum, but do not in a hydrogen-chlorine flame. There is probably metallic vapor in some flames, which tends to the dissociation of exothermic compounds in flame. This was proved by the precipitation of metallic mirrors from flames striking a water-cooled porcelain tube. This was illustrated by producing in a Bunsen flame mirrors of copper, silver, bismuth, antimony, arsenic, lead, tin cadmium and zinc. Molybdenum and tungsten salts do not give mirrors in the Bunsen flame, but fine mirrors of these metals were obtained from the oxy-hydrogen flame. Even sulphur can be thus precipitated on cold porcelain from sulphur dioxide, and red phosphorus from phosphorus compound.

We thus have evidence that many reactions take place in flames, and different reactions may cause the emission of different colors. For example, copper changed to cuprous ions in flame gives a green color; cuprous salt changed to cupric salt colors the flame blue; cuprous ion changed to cuprous salt colors the flame red. Tin changed to stannous salt gives carmine, but stannous salt to stannic salt gives green.

Many rapidly occurring chemical reactions emit light, and this is not confined to reactions taking place at high temperatures. Thus phosphorus oxidized by hydrogen peroxide gives colored phosphorescent light. Bromine oxidized by pyrogallol gives pale orange light. Mercury heated in bromine flame vaporizes at a very low temperature in an orange flame. This very clever experiment was beautifully performed.

Finally, the oxidation of bromine at an anode in potassium bromide solution, with a current voltage of only two volts was shown to give an orange-yellow glow at ordinary temperature.

W. D. BANCROFT

Professor Bancroft closed by stating that as a working hypothesis it appears that the conversion of the energy of the chemical reaction in a light increases as the temperature is lowered, and vice versa, thus explaining the common occurrence of luminescence at very low temperature as observed by Dewar.

Professor Bancroft's lecture was discussed by Messrs. Hambuechen, Tucker, Northrup and Whitney.

### Electric Steel Castings

Mr. C. A. Hansen, of the General Electric Company, then presented in abstract two papers on the electric furnace in the steel foundry, one by himself, the other by Mr. E. B. Clark, president of the Buchanan Electric Steel Company of Buchanan, Mich.

Mr. C. A. Hansen gave in his paper the results obtained with a 2-ton three-phase arc furnace in use since 1911 in the foundry of the Treadwell Engineering Company at Easton, Pa., which had taken over the work of an old crucible steel castings plant, making light section castings.

The cost of melted metal from the electric furnace was found to be somewhat less than one-half that of the old crucible furnace plant when the latter was using oil at 2½ cents per gallon. Since the advance in the price of oil has added $6.00 to $7.00 more to the cost per ton of molten crucible steel, the possibilities of saving in costs is readily apparent.

So far as the product is concerned, the most striking differences are not found in comparing electric and crucible steels of similar compositions. If any differences exist between such steels, they are negligible in importance, as repeated tests have shown.

Electric steel castings are usually made in lower carbons than it is possible to make from even clay-lined crucibles. In the latter it is perfectly possible to melt 0.20 carbon steel, but it is not possible to run the 0.20 carbon product regularly into light-section castings. As a result, 0.30 to 0.40 carbon castings are the usual output of the crucible steel foundry, and all castings which require machining must be annealed.

With the electric furnace, furnace maintenance costs increase rapidly as the carbon content of the product is brought down, and, quite contrary to current opinion, it is not economical to turn out 0.10 carbon steel castings, although it is perfectly possible to do so.

It is, however, economically practicable to turn out 0.20 carbon castings, and such castings can be machined easily without annealing. There is little question that all castings, whether 0.20 carbon or 0.30 carbon, can be improved by annealing, but the American attitude seems to be against the expense of annealing where annealing can be avoided.

Many have suggested charging molten cupola metal directly into the electric furnace for refining. In several such cases of which the author knows, the power consumption per ton of output was greater for the cupola metal charge than for the cold scrap charge; the original cost of the cupola metal was in the neighborhood of $18 per ton, as compared with $12 per ton for the regular cold charge, and the cost of furnacing was likewise higher for the cupola metal charge. The economy incident to heating the furnace with auxiliary fuel-burning apparatus may interest those who charge molten metal into electric furnaces, but the interest attaches rather to the prevention of skulled furnace bottoms than to a direct saving in electric energy. Heating the furnace and charge to a good red heat by means of oil burners (with oil at 2½ cents per gallon) increased the cost $1 per ton over the regular practice of all-electric heating. Keeping the furnace hot over night by means of either oil or electric energy was found not to materially decrease maintenance costs, and it did increase the cost of production. These items above refer to power supply at approximately 1 cent per kw-hour.

Much stress has been laid on the economy attaching to continuous operation of the electric furnace as compared with mere day-shift operation. So far as costs go for the molten steel, it is true that continuous operation means 10-15 per cent saving over intermittent operation. Very little has, however, been said regarding the relative efficiencies of day and night work in the other departments of the foundry, nor has it been well impressed upon the mind of the average investigator of electric steel problems that one can easily lose many times the 10-15 per cent saving in molten metal costs in the decreased efficiency of the night shifts on the molding floor, cleaning room, etc.

Claims are being made that 10 to 12 heats from cold scrap can be taken from one electric furnace in 24 hours. Possibly they can, but the furnace will have to be rebuilt at least three times each week.

These and other considerations have led to the practice, now established at Easton, of operating the foundry on day shift only, charging a good quality of steel scrap, enough pig and ore being added to keep the charge off the furnace bottom, and casting steel of around 0.20 carbon, unless otherwise specified.

The furnace plant has been operated on a one-heat-per-day basis, requiring 7 to 7½ hours to turn out its charge from the cold furnace. Power consumption at furnace transformer primary terminals has, in that case, averaged 1050 kw-hours per 2000 lb. (909 kg) steel in the ladle.

The furnace has been operated also on a two-heat-per-day and three-heat-per-day basis, when business conditions warranted. The second and third heats, having the advantage of being started off in a hot furnace, are finished in 4½ hours, at a current consumption of 630 to 640 kw-hours per ton. Even with the three heats per day, no steel is poured outside of the regular day shift. Two men start the furnace shortly after midnight, and steel is poured at 7.15 a. m., 11.45 a. m. and at 4.30 p. m. The uncertainties attaching to pouring on schedule time are not as great as they are with either open-hearth or crucible furnaces.

The load curve for the furnace here considered is smoother and of higher power-factor than the load of similar magnitude used in the shops of the Treadwell company where the products of the steel and iron foundries are machined.

Mr. Treadwell has recently sent the following additional data concerning his furnace:

| | |
|---|---|
| Average number of heats per week | 15 |
| Average weight per heat | 4600 lb. |
| Average power consumption per 2000 lb | 900 kw-hour |
| Average repair costs per 2000 lb | $2.50 |
| Average electrode costs per 2000 lb | $2.50 |
| Average weight castings made | 9 lb. |
| Ratio of cleaned castings, risers, etc., to charged weight, | 92-95 per cent |
| Ratio of finished castings to charged weight, | approximately 60 per cent |

The furnace lining is repaired after 35 heats.

Mr. Treadwell is a firm believer in pouring extremely hot steels, and this fact is reflected in the high maintenance costs and in a rather high power-consumption.

A similar furnace, of which Mr. Hansen has accurate records, shows costs as follows:

| | |
|---|---|
| Power consumption per 2000 lb | 725 kw-hour |
| Repair costs per 2000 lb | $1.30 |
| Electrode costs per 2000 lb | $2.15 |

The latter furnace is pouring somewhat colder metal into castings of 15 lb. average weight, and repairs to the furnace lining are made after 8 to 10 weeks' operation on the same basis of fifteen heats per week. In the latter case the repair charges include upkeep of the bottom-pour ladles used, and this is believed to be also the case with Mr. Treadwell's figure.

### Electric Furnaces for Steel Making

Mr. E. B. Clark, in his paper on this subject, says that the intending user of an electric furnace wishes dependable answers to two questions:

First.—How will an electric furnace compare with some other apparatus for producing or refining steel as to quality of output and cost of operation?

Second.—Assuming the wisdom of an electric furnace installation, what is the best type of furnace, and what size of unit is proper?

The author compares the electric furnace, the crucible furnace, the Tropenas converter, and the open-hearth furnace.

The crucible furnace enables one to make accurate alloy mixtures of high quality without contamination from gases or furnace linings. Practically no refining can be done and therefore high-grade materials must be used for the mixture. By the law of supply and demand, the price of pure materials for use in crucible furnaces will be higher where the crucible process is employed to a considerable extent. The electric furnace will produce steel of the same degree of purity as a crucible furnace, and the possibility of refining in an electric furnace makes possible the use of less pure materials. This is an advantage for the electric furnace and, at the same time, an advantage for the crucible furnace, because the demand for the high grade materials necessary in the crucible process is reduced by each additional electric furnace installation and therefore the price of the charge for the crucible furnace is reduced. This is especially true as applied to the small crucible furnaces used in foundry practice, which require low-phosphorus steel punchings for their successful operation.

The small Bessemer converter, or Tropenas vessel, is capable of producing hot steel in small units quickly. It does not permit of refining, however, and therefore, necessitates the use of low phosphorus and low sulphur pig iron which must be pre-melted in a cupola, using high-grade coke. The losses are severe and the steel is not free from oxides and occluded gases. The electric furnace will produce steel just as hot as the small Bessemer vessel, but free from oxides and occluded gases. However the electric furnace requires scrap for charging rather than pig iron, so if only pig iron is available at commercially desirable figures, the pig must be converted into steel before charging into the electric furnace.

The open-hearth furnace will produce from pig and scrap, steel of a fairly high degree of purity and of fairly high temperature. The electric furnace will do the same thing (except that the use of a large percentage of pig is not desirable) and is capable of producing purer and hotter steel than is the open-hearth under usual operating conditions.

Summarizing these general observations, it may be said that for the alloying of steels the electric furnace offers nothing that the crucible furnace does not; for the production of a very hot steel an electric furnace offers nothing that the Bessemer converter does not; and metallurgically speaking, the electric furnace offers nothing that the open-hearth does not. It is a fact, however, and this is the important fact, that the electric furnace combines in itself certain advantages of all three of the other processes mentioned. On the other hand, it is seldom that one wishes to secure the advantages of all these other three processes combined in one.

For the electric furnace the cost of power is not of supreme importance. Experience is more important. The electric furnace is a more delicate apparatus than any of the other three furnaces mentioned. Electric furnace operation has not yet been reduced to standard practice. Melters familiar with its operation are scarce and difficult to find.

Mr. Clark then gives an account of his experience with two electric steel furnace types. One is a 1 to 1½-ton furnace of the Stassano surface-arc type, the other a 5-ton furnace of the Heroult submerged-arc type.

"To summarize our views upon the relative merits of the two types of furnaces, as based upon our own experience, I would say that we have found the surface-arc type to be a much better furnace than its critics would have one believe. On the other hand, we have found the submerged-arc type better for our purposes because of its larger capacity and lower cost of operation. It would not be fair, however, to ascribe the lower costs entirely to its type, for the capacity of a unit certainly has much to do with the lower cost. Where a foundry is, like ours, entirely dependent for its supply of hot metal upon the electric furnace, this type is better by reason of less necessity for lining repairs."

"In conclusion, I wish to reiterate my statement that an intending user of an electric furnace may expect to learn much more about the furnace by his experience after he gets it than by the statements of someone who wishes to sell him a furnace."

### Discussion on Electric Steel

The two papers by Mr. Hansen and Mr. Clark elicited quite a lively discussion.

Mr. H. D. Hibbard said the two papers are valuable as an account of actual practice. He thought that operators of electric steel furnaces often use too high a temperature.

Mr. Ernest Humbert protested against the concluding remarks in Mr. Clark's paper as a reflection on sellers of electric furnaces. Electric-furnace steel is fully equal to the best crucible steel. While good steel castings can be made in crucibles, it is not possible to make them low in carbon. As to the scarcity of skilled electric melters, he had himself trained quite a number of men reliably in a short time in electric-furnace operation. It takes quite some time to produce a good open-hearth melter. He thought that an advantage of the Heroult type over the Stassano type is that in the former the roof is subjected to less heat by radiation.

Dr. K. G. Frank gave figures on the progress of the electric steel furnace in Europe, especially in Germany and Austria, which has been much more rapid and satisfactory than in this country. He thought American steel makers had not attacked the electric steel furnace problems with the same thoroughness and attention to detail.

Mr. Henry Hess spoke of his satisfactory experience with a Stassano furnace in making steel castings during several months and, contrary to Mr. Humbert's statement, they have had no trouble at all with their magnesite roof.

Mr. C. A. Hansen thought that Mr. Clark after having operated a Stassano furnace had applied his experience obtained with the latter to the operation of a Heroult furnace. This is a mistake as there is an essential difference between the two types. A characteristic feature of the Stassano furnace is the independence of slag. The Heroult furnace is not independent of the slag and it is important to avoid fluctuations of power supply.

Dr. J. W. Richards said that electric-furnace roofs are not always of silica as had been intimated. Stassano uses a magnesite roof. Aluminium nitride may also be considered as a suitable material. He agreed with Dr. Frank that the more rapid progress of the electric furnace in Europe is due to the greater patience exercised there.

Dr. C. G. Schluederberg said that at a recent visit to the Latrobe Steel Castings Company he had seen several runs with manganese steel in a Heroult furnace and had been impressed with the very uniform load curve.

Mr. C. A. Hansen remarked that crucible steel castings are not all now what they used to be. They are not always dead melted. The electric furnace has one important advantage for large production, that is the possibility of knowing exactly what you are pouring before you pour. With converter and crucible steel castings you must rely on guess work and this results in nonuniform metal. The main thing in a new electric-furnace plant is to establish a practice. The trouble is now that high-priced men accept positions as electric-furnace melters at a low salary simply to get the experience, and when they get it they leave and the training of a new melter has to begin all over again.

Mr. E. L. Crosby said that the Detroit Edison Company had made a special rate for electric steel at ¾ cent per kw-hour or less, according to the hours in which the current is used.

Mr. F. A. Lidbury remarked the electric steel furnace was an example of the possibility of using the electric energy of central stations during off-peak hours.

Mr. C. A. Hansen said from his experience that with one heat a day it cost $80 per ton to make a ½-ton heat and $27 per ton to make a 15-ton heat, while with two heats per day the cost for a ½-ton heat is $60 per ton and $19 per ton for a 15-ton heat.

Mr. R. Turnbull thought the figures for the ½-ton heats were high. Mr. W. McA. Johnson suggested Mr. Hansen's salary might be in the overhead charges.

Mr. E. F. Cone emphasized the physical and chemical superiority of electric steel castings, due to the greater refining possibilities of the electric furnace. The chemical purity is greater, the tensile strength and elastic ratio are improved, and not only the static but the dynamic properties of the steel are better.

Mr. Hess thought that steels of exactly the same composition would have the same properties and that it would not matter whether the heat had been applied electrically or otherwise.

Mr. Hansen said that comparative tests of electric steel and open-hearth steel at Schenectady had shown no essential difference in properties.

Dr. Richards stated that the refining action of the electric steel furnace must result in superior castings and Mr. Cone added that it was self-evident that the purer a steel the better its qualities, and that the higher purity of electric furnace steel could not be questioned.

Mr. Wm. D. Mainwaring said that steel must be mixed thoroughly and the time factor must be taken into consideration. In his 15 years' experience in steel making with all kinds of furnaces he had seen some of the poorest steel made in electric furnaces and had seen some of the best made in that furnace. It is necessary to work steel right in all kinds of furnaces.

Mr. Hibbard thought that the hearth on which the steel is made should be taken into consideration. In the crucible it is graphite, in the open-hearth iron oxide, while the electric furnace has a basic bottom.

### Metallurgy of Zinc

The following two papers were read by title only as they had already been read before the New York Section of the Society; long abstracts of the same were given on pages 677 and 678 of our Vol. XI (December, 1913):

"Improvements in the Metallurgy of Zinc," by G. C. Stone.

"Electric Zinc Smelting," by W. R. Ingalls.

Contrary to expectations there was no discussion.

### Advantages of Southeastern Alaska for Hydroelectrochemical Industries

An article by Mr. W. P. Lass called attention to the natural resources of Southeastern Alaska for that class of industry which requires cheap hydroelectric power. The unsettled policy of the Government regarding the exploitation of Alaska has hindered development in that country; but more recently the Government's attitude is more clearly defined. It is impossible to get perpetual title to water rights, but 50-year permits for the use of water, subject to renewal, may be obtained by the payment of nominal fees not exceeding $1 per horsepower year.

Southeastern Alaska presents a network of navigable bays and inlets with shores rising to an altitude of two or three thousand feet. Lakes situated high in the mountains afford an easy means of conserving precipitation and equalizing flow.

At the present time only a very few of the available waterpower sites have been developed. One of these, the Speel River project, can develop all-year power to the extent of 1000 hp. The cost of generating is estimated at not to exceed $5 per horsepower year, and the cost of installation at less than $50 per horsepower.

The country has economic deposits of such raw materials as limestone, marble, gypsum, silica and pyrites. There is also high-grade semi-bituminous and anthracite coal, as well as producing oil wells and a refinery. There are known deposits of iron ores in Alaska, and the electric production of pig iron is a possible industry on account of the availability of cheap power and the abundance of charcoal.

The author believes that Alaska offers the same advantages as Norway for the establishment of electrochemical industries, with the exception of the cost of labor, which is $3 to $4 per day. Among the manufactures which the author considers possible in Alaska are electric smelting of iron and non-ferrous minerals, the production of sulphuric and nitric acids to be used in the manufacture of wood pulp, paper, and phosphate fertilizers. Cyanide and powder are also in demand and can be manufactured in Alaska for use throughout the West.

Another possible industry is the manufacture of potash salts from kelp.

### Leaching Copper Ores at Chuquicamata, Chile

The feature of the Saturday morning session held in Earl Hall, Columbia University, was an illustrated lecture by Mr. **E. A. Cappelen Smith**, consulting engineer with M. Guggenheim Sons, on the progress of experimental work in the treatment of oxidized copper ores from Chuquicamata, Chile. The investigations have been carried out under the direction of Mr. Smith during the past year on a large scale for the purpose of determining the metallurgical details of the 10,000-tons-a-day plant to be erected in Chile.

E. A. CAPPELEN SMITH

In view of the importance of this lecture we print it in full on page 291 of this issue and also comment on it in our editorial pages.

Mr. Smith exhibited the fused magnetite electrodes used as anodes and originally invented by the German Griesheim Company for their use in their cells for electrolysis of brine.

The lecture was discussed by Messrs. Richards, Addicks and Lidbury.

### The Hydroelectrolytic Treatment of Copper Ores

This paper by Mr. **Robert R. Goodrich** gives a brief summary of hydro-electrometallurgical copper processes and a review of the literature on that subject. The author classifies the hydro-electrometallurgical process into two groups: First, purely chemical methods such as alkali, sulphite, sulphate and chloride processes; and second, electrolytic methods such as sulphate and chloride processes. The paper consists mainly of brief descriptions of different processes according to above classification.

### Leaching of Copper Tailings

A paper by Dr. **Rudolf Gahl** gives the results of some leaching tests made at Morenci, Ariz., in connection with the concentrating plant of the Detroit Copper Company. The author calls attention to the changing sentiment among the engineers regarding the feasibility of leaching copper ores. The water-concentration processes have not given satisfactory recoveries of metal, particularly in those cases where there is a mixture of sulphide and oxidized copper minerals.

The loss of the latter is very high, particularly in slime tailings.

The author advocates the counter-current continuous decantation process, as developed in the cyanide industry, as the best method of leaching and washing copper slimes.

The work at Morenci resulted in the recovery of 60 per cent of the copper contained in the slime tailings, this recovery representing the copper existing in the oxidized state. A higher extraction could have been obtained by using ferric sulphate in connection with sulphuric acid.

The probable operating costs of a leaching plant for slime tailings were calculated on the basis of the experiments, with a certain margin for safety. They are represented below. The tailings slime being ordinarily a waste-product was considered not to cost anything.

Probable Cost of Leaching Tailings Slime per Pound of Copper Delivered at New York

| | |
|---|---|
| 3.50 lb. acid, at $10 per ton $H_2SO_4$ | 1.75c. |
| 1.50 lb. of scrap iron, at $19 per ton | 1.43c. |
| Power | 0.25c. |
| Labor and repairs | 1.00c. |
| Smelting, refining, transportation of Cu, including losses in smelting, etc | 2.00c. |
| Interest and depreciation of plant | 1.00c. |
| Total | 7.43c. |

The figures are based on conditions prevailing at Morenci, Ariz., where the tests were made. Owing to the location of this mining camp freight rates are rather high.

Since making the leaching tests the flotation process has been applied to the same material with considerable success in saving the sulphide portion. The author concludes, therefore, that for certain classes of copper ores the combination of a flotation and a leaching process consitutes a form of treatment that would be difficult to surpass.

### Metal Inventory in an Electrolytic Copper Refinery

A paper by Mr. **Ralph W. Deacon** giving in complete detail the methods used in an operating plant for a number of years, in taking regular inventories of metal. The taking of the inventory is divided into sections, each operating department accounting for all metal on hand at the inventory moment or "cut off."

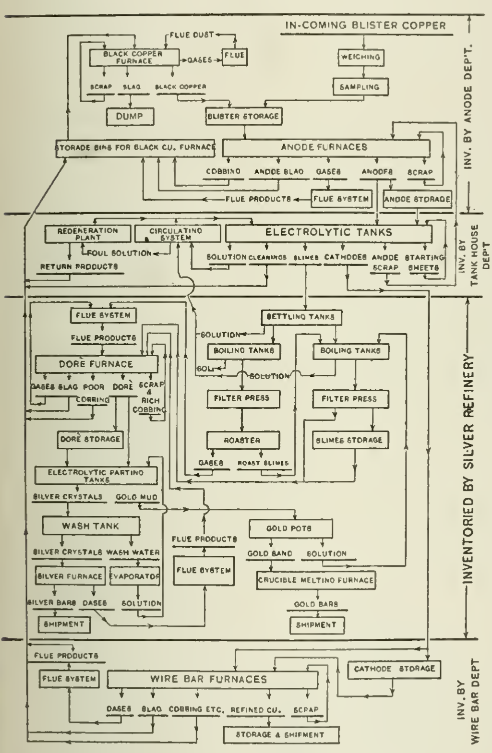
"Cut offs are made between each department and between sub-units within each department, and for materials going in each direction, and each department or sub-unit is held responsible for the proper handling of the 'cut off' of both incoming and outgoing material, with especial emphasis placed on the incoming 'cut off.' That is, a department is not relieved of the responsibility of seeing that the 'cut off' on outgoing materials is correct, but the initiative in this respect is expected to be taken by the department receiving the material, i. e., the incoming 'cut off.' This has so worked out that any trouble due to mixup in proper 'cut offs' is entirely unknown."

There are four separate inventories grouped, as shown on page 339. "In general the anode department accounts for all metals between the stages of arrival at the plant and delivery in anode form to the tank house. The latter then accounts from this point to that of delivery of cathode copper to slimes. The wire-bar department accounts from the stage of cathodes received to refined copper shipped, and the silver refining department, from slimes received to fine gold and silver shipped."

### Electrolytic Zinc

A paper by Professor Jos. W. Richards on the electrolytic deposition of zinc was read by title as it has been already presented before the New York Section of the Society. It is a review of a recent lecture by Dr. Victor Engelhardt on the subject, with critical remarks by the author.

FLOW SHEET OF ELECTROLYTIC COPPER REFINERY



DEPARTMENT INVENTORY OF COPPER REFINERY

### Addition Agents in the Deposition of Zinc from Zinc Sulphate Solution

A paper by Messrs. O. P. Watts and A. C. Shape gives the results of experiments with forty-two different organic substances in a zinc-plating solution.

The electrolyte was made by adding an excess of zinc to dilute sulphuric acid. The solution had an acid reaction and contained 25 per cent of $ZnSO_4.7H_2O$. The amount of organic substance added was 1 gram per liter. The solutions were electrolyzed for two hours at about 22 deg. C., with a zinc anode and an iron cathode, at a current density of about 10 amperes per square foot (1.1 amperes per sq. dm.). For comparison, the well-known Meaker galvanizing solution was electrolyzed under similar conditions. The majority of the substances added had an injurious rather than a beneficial effect upon the deposit. The most common defect was the production of vertical grooves or striations.

The general result of these preliminary experiments was the discovery of three promising addition agents for the deposition of zinc from a solution of zinc sulphate, namely, eikonogen, pyrogallol and betanaphthol.

### Electrodeposition of Cadmium

Two papers, by Professor Frank C. Mathers, and Mr. Hugh M. Marble, of Indiana University, deal with the electrodeposition of cadmium.

The first paper gives a review of the existing literature on the electrodeposition of cadmium and is divided into four chapters, dealing with cadmium salts of inorganic acids, ammoniacal solutions, cadmium salts of organic acids, commercial plating and refining respectively. In almost all cases crystalline rough deposits were obtained.

In the second paper the authors give the results of their own original experimental work in which an attempt was made to determine what salts of cadmium are best suited for giving smooth, non-crystalline deposits. Baths containing equivalent weights of the different salts of cadmium were electrolyzed under the same conditions. The cathodes from the ammoniacal and the alkaline tartrate baths were hopelessly spongy. The deposits from the acetate, bromide, iodide, sulphate, phosphate and chloride solutions were rough and crystalline. Many experiments were tried with the chloride solutions. A bath containing 4 per cent cadmium as the chloride, 10 per cent ammonium chloride, 5 per cent hydrochloric acid (by volume) and 0.1 per cent peptone gave a fairly smooth, finely crystalline deposit. A bath of the same composition as that just given, with the addition of 10 per cent ferric chloride, gave a much better deposit. Manganese, aluminum or chromium chlorides did not improve the deposit in the same way that the iron did. None of these deposits were equal to those described below. In the few experiments that were tried with the bromide and iodide solutions, the deposits were more crystalline and rough than with the chloride baths.

Fluoride, fluosilicate, fluoborate or perchlorate solutions containing 4 per cent cadmium, with 0.5-5 per cent free acid and 0.2 gm. peptone, glue or phloridizin, or 4 drops of clove oil, gave excellent, smooth deposits. Not all of these addition substances were tried with all of the above cadmium salts, but in all cases where they were tried excellent deposits were obtained. Sometimes spongy places or spots were formed upon the cathodes. Some rough projections also gradually formed on some of the cathodes. It is thought that these rough places were produced by particles of slime, which became detached from the anodes in spite of the wrappings of filter paper. Amalgamation of the anodes completely prevented slime from becoming detached, but this scheme was tried only in the quantitative experiments.

These experiments again demonstrate the value of "addition agents," since smooth deposits of cadmium could not be obtained without their use. The same addition substances—clove oil, glue, peptone and phloridizin—which were found to give good lead deposits are the only valuable ones for cadmium deposition.

Cadmium is much more difficult to obtain in a smooth condition than lead.

There was a gradual loss of free acid in the baths, due to chemical solution of the anode. This had little effect upon the deposits, since only a little free acid is required in the solutions.

### Electrodeposition of Nickel

A paper by **Dr. C. W. Bennett, Mr. H. C. Kenny** and **Mr. R. P. Duggliss**, of Cornell University, on the electrodeposition of nickel reaches the following results:

A good deposit of nickel may be obtained from the double sulphate if the solution at the surface of the cathode is kept alkaline.

The efficiency is dependent upon the degree of alkalinity of the cathode film.

The efficiency can be started high and maintained high by adding a definite amount of ammonium hydroxide to the solution.

The alkaline solution film at the cathode may be disturbed and the efficiency of deposition decreased by stirring the solution vigorously.

Since alkalinity is necessary for good efficiency, it is very probable that in acid solutions nickel is deposited only when impoverishment of the hydrogen ions has caused the solution to become alkaline and given the conditions under which nickel may deposit.

The iron content of a deposit formed on a rotating cathode is greater than that formed on a stationary electrode. This may be due to mechanical occlusions.

The iron content of the anode does not materially affect the efficiency.

### Electrolytic Deposition of Brass

A paper by **Dr. C. W. Bennett** and **Mr. A. W. Davison**, of Cornell University, on the electrolytic deposition of brass on a rotating cathode, reaches the following conclusions:

Measurements were made of the voltages required to deposit copper and zinc from a number of solutions with rotating cathodes, the voltages being measured against an oxygen electrode. Those solutions giving similar curves were studied with a view to obtaining a good deposit of brass. A brass was not obtained in any case, except from the cyanide solution.

The deposition of brass from cyanide solution is probably due to two factors: First, the tendency for the potentials of copper and zinc to become the same in the cyanide solution, and, second, the increase in the potential of the more noble metal by impoverishment. The latter factor is practically eliminated by using the rapidly rotating cathode.

A satisfactory brass has not been deposited from the cyanide solution on the rotating cathode. The brittleness of the alloy is probably due to occluded impurities. Hydrogen was removed from the alloy by heating in alkali. The disturbing factor probably arises from the cyanide itself, which it seems impossible to eliminate.

The effect of impoverishment has been shown by showing that a brass may be obtained up to a limiting speed of rotation of the cathode, beyond which zinc alone is deposited.

The metal ratio of copper to zinc in solutions for the deposition of a brass varies not only with variations of free cyanide, but also with the rate of rotation of the cathode.

### New Method for the Determination of Free Cyanide In Electroplating Solutions

A paper by **Mr. Gustave E. F. Lundell** proposes a new method for the determination of free cyanide.

"Briefly stated, the new method consists in titrating an ammoniacal cyanide solution containing a small quantity of dimethyl glyoxime, with standard nickel-ammonium sulphate solution until a permanent red precipitate is produced. The reactions involved are expressed by the equations:

$$NiSO_4 + 4KCN = K_2Ni(CN)_4 + K_2SO_4$$
$$NiSO_4 + 2C_4H_8N_2O_2 = Ni(C_4H_7N_2O_2)_2 + H_2SO_4$$
$$H_2SO_4 + 2NH_4OH = (NH_4)_2SO_4 + H_2O$$

"No permanent red precipitate of nickel dimethyl glyoxime is formed until all of the free cyanide has been used up in the reaction expressed by the first equation. Free sulphuric acid hinders the precipitation of nickel dimethyl glyoxime, hence the ammoniacal cyanide solution."

The solutions required are a standard solution containing 15.3 grams of nickel-ammonium sulphate, in water containing 5 cc. concentrated sulphuric acid, diluted to 1 liter and a dimethyl glyoxime solution containing 8.9 grams of dimethyl glyoxime in 1 liter of 95 per cent alcohol.

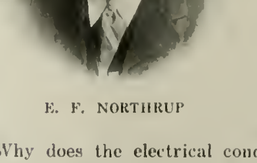
The method of analysis is as follows: A measured volume of the electroplating solution is diluted to 100 cc., treated with 1 cc. of ammonium hydroxide, 1 cc. of the dimethyl glyoxime solution, and then titrated to a permanent red precipitate with the standard nickel-ammonium sulphate solution. The color play toward the end of the reaction resembles that seen in the titration of an alkaline methyl-orange solution with an acid solution. For the sake of accuracy, and also convenience, the volume of electroplating solution taken should contain from 0.2 to 0.5 gram of free cyanide.

The author states that the new method is more rapid and accurate than other methods and has greater freedom from interferences.

### Electric Conduction at High Temperatures

The session of Saturday afternoon, held in the lecture room of the School of Mines, Columbia University, was opened by a lecture, illustrated by many lantern slides, by **Dr. Edwin F. Northrup**, of Princeton University, on "Electric Conduction at High Temperature and How to Measure It."

The older physics recognized matter and energy as the two objective realities but the newer physics adds electricity as a third objective reality. The transference from one point in space to another of unelectrified matter, or of electromagnetic energy forms no part of the problem of electric conduction which is confined to the transference of electricity.



E. F. NORTHRUP

The problem of electricity must answer the two questions: (a) Why do different materials have a different electrical conductivity at the same temperature? and (b) Why does the electrical conductivity of a given substance change when the temperature changes?

These questions can only be answered in a satisfactory way, without unwarrantable extrapolation, by examining the experimental facts of conduction over a very wide range of temperature. By far the greatest number of facts of conduction have been examined in the temperature range, 0 deg. to 100 deg. C., which is but about 2½ per cent of the temperature range which has been experimentally realized.

A slide showing the temperature scale was shown, which revealed the restricted range of temperature to which most scientific inquiries are confined, and it was pointed out that nature grows less complex as we depart in either direction from the temperature at which organic life exists; that by studying conduction at high temperatures many complexities become eliminated which permits us to better understand electrical conduction at temperatures where we use it; and that the sharp distinction we are accustomed to make between conductors and insulators only belongs properly to the lower half of the highest temperature range obtainable—from 0 deg. to 4000 deg. absolute.

The leading facts of conduction now known were summarized. The work of Onnes, who showed that some pure metals have infinite conductivity at about 4 deg. absolute, were referred to and his curves were shown. At low temperatures the insulators have infinite resistivity while the alloys are intermediate in resistivity.

At elevated temperatures comparatively few facts are known regarding conduction on account of the experimental difficulties heretofore met with in making accurate measurements. These experimental difficulties being in large part now removed, we are able to show the characteristics of the conduction of nonmetallic solids and the conduction of metals in the solid and molten state to temperatures as high as 1500 deg. C.

Slides were shown (six made by Dr. Sommerville and ten by Dr. Northrup) giving curves which accurately express the variation of resistivity with temperature of several oxides of the metals and of the pure metals Na, K, Hg, Cd, Pb, Zn, Sn, Bi, Sb, Cu, Al, Au, and of the alloys Na+K, and brass. It was pointed out that all of these metals and alloys with the exception of bismuth and antimony, suddenly increase in resistance in passing from the solid to the liquid state.

In general the ratio of the resistivity just after fusion to the resistivity just before fusion, is roughly 2.

This ratio for bismuth is 0.478 and for antimony about 0.75. Both of these metals contract on liquifying.

With the exception of zinc, cadmium and antimony, the increase in resistance with temperature of the metals in the molten state is very nearly linear. In the case of gold and copper, which were examined to over 1450 deg. C., the increase in the molten state is exactly linear.

Methods for making these measurements were then considered under the headings—Methods of producing the temperature, of measuring the temperature and of making suitable holders for refractory materials at temperatures where everything conducts and for metals in the molten state. A large and small model of the new "Northrup high-temperature furnace," in which platinum may be melted, were exhibited and their construction explained and uses demonstrated. This has been described in detail in this journal. A slide was shown of the veteran furnace in which many measurements were made to temperatures as high as 1600 deg. C. and under.

Slides were shown of a new device, called a "cascade attachment," which may be quickly placed in the large type furnace and by means of which a temperature may be readily obtained which will melt tungsten, or even vaporize carbon. (See also the article by Dr. Northrup on this subject on page 305 of this issue). Any lower temperature can also, by its means be obtained and held. It was pointed out, that because of the black-body conditions obtained and the fact that the heated zone can be directly looked into without an intervening window of unknown light-absorbing power, radiation at temperatures blending into that of the arc may be conveniently studied.

A summary of the facts of conduction at high temperatures was given and a chart shown which summarized the special characteristics of the metals. The interesting relation was brought out that for six of the metals, for which data have been obtained, the ratio of the coefficient of resistance to the coefficient of cubical expansion of the metal when in the molten state, is approximately constant; that this holds true for potassium and tin; though the former has ten times the expansion of the latter.

Suggestions were then given for investigations on the subject of conduction which are important for the future. The most important of these suggestions being that the cubical expansion coefficients of molten metals should be determined and that the resistivity should be studied of metallic vapors when near their critical temperature and pressure. The speaker expressed his belief that we do not yet know enough facts of electric conduction and related physical properties over a wide range of temperature to make it possible to formulate a satisfactory theory of conduction and that present theories are certainly inadequate to explain the facts of conduction as they have been observed at the low temperatures at which Onnes worked, to the temperature of 1500 deg. C., at which accurate data for some of the metals have been obtained.

### Electric Properties of Silver Sulphide

Mr. F. A. J. Fitz Gerald, of The Fitz Gerald Laboratories, Niagara Falls, N. Y., followed with a very interesting paper, entitled "Laboratory Notes on Some Electrical Properties of Silver Sulphide," and illustrated by lantern slides and some pretty experiments. The study of the electrical properties of silver sulphide was undertaken by the author in connection with the commercial development of an automatic fire alarm invented by Mr. E. Garretson.

The conclusions of Mr. Fitz Gerald's paper are as follows:

Silver sulphide is a solid electrolyte well worthy of study, since it lends itself admirably to experiments having for their object research on the properties of electrolytes of this class.

The temperature-resistance curve of silver sulphide shows a critical point at a certain temperature, but this is not the same on the heating and cooling curves.

The temperature-resistance curve of silver sulphide is strongly affected by impurities. Thus pure silver sulphide gives a critical point with rising temperature at 170 deg., sulphide from an alloy containing 0.5 per cent copper has a critical temperature of 163 deg., and that made from the 7.5 per cent allow a critical temperature of 104 deg. In this relation it is interesting to note that Northrup has found a critical temperature for alundum at 1100 deg.

Silver-silver sulphide and copper-silver sulphide form thermoelectric couples, the effect of which must be looked for in experimental work on silver sulphide.

Even very slight chemical reduction in a mass of silver sulphide has a great effect on its electrical resistivity.

Lack of homogeneity in the sulphide made from silver-copper alloy has an important influence on its electrical properties. The resistivity is greatly affected, and probably also other characteristics such as the thermoelectric and rectifying effects. Much of the experimental work on this point has not been mentioned because it is of too incomplete a character, but the observations made are such as to warrant a warning. This would probably explain certain anomalies which may be found in the case of mixed sulphides. These anomalies are comparable to the case of alloys where there may be a "false resistance" due to thermoelectric effects, as pointed out by J. J. Thomson.

Electrolysis may occur in a Cu — $Ag_2S + Cu_2S$ — Cu cell in a 25-cycle A.C. circuit, with the result that the cell is eventually short-circuited. On the other hand, if silver electrodes are used the cell is not short-circuited.

Electrolysis in the Cu — $Ag_2S + Cu_2S$ — Cu cell is probably due to a persistent rectifying effect. This rectifying effect is very marked in a cell where one copper electrode is coated with cupric oxide.

A rectifying effect may also be shown with an Ag — $Ag_2S + Cu_2S$ — Ag cell, but after being in an A.C. circuit for some time this disappears.

In the Ag — $Ag_2S + Cu_2S$ — Ag cell showing a rectifying effect there is a critical temperature at which this disappears on heating, and a different critical temperature at which it reappears on cooling. These critical temperatures may be correlated with the critical points of the temperature-resistance curves. Study of this phenomenon might throw some light on the nature of conduction in solid compounds, whether this is electrolytic or electronic or both.

### Polarization Single Potentials

A paper by **Mr. Claude N. Hitchcock** gives an account of an investigation carried out at the University of Wisconsin with reference to a former experiment of Dr. J. W. Richards, who obtained decomposition of water at an impressed e.m.f. of only 1.15 volts, instead of 1.67 volts, the generally accepted value of the decomposition voltage of water. This result had been obtained by the use of platinum electrodes differing greatly in size. The present author's investigation was undertaken for the purpose of determining the potential at each electrode in such cases of decomposition of electrolytes below the normal decomposition point.

The conclusions reached are as follows:

Decomposition of water can be accomplished at any voltage with platinum electrodes, provided the latter are of the proper size.

The oxygen normally present in laboratory reagents is sufficient to produce marked depolarization at the cathode.

The single potential of each electrode so depends on that of the other that any change in one, due to disturbing influences, is counteracted by such a change in the other that, below the decomposition point, the sum of the separate electrode polarization equals the total polarization, and this in turn equals (very nearly) the impressed electromotive force.

Any desired current may be passed through an aqueous solution of sulphuric or hydrochloric acid without causing evolution of gas, provided the electrodes are made large enough.

The evolution of gas at the electrodes depends on the total current density minus that part of the current density neutralized by the action of depolarizing agents.

### Determination of Free Energy

Dr. Reinhard Beutner, of the Rockefeller Institute of Medical Research, New York City, presented a paper on a "new cell arrangement for direct determination of free energy." This paper gives the results of a continuation of the researches which the author has described in former valuable papers before the society.

In his present paper it is shown how galvanic elements can be arranged so as to measure, without transfer potential, the free energy of reactions between solid salts and metals or between solid salts alone. These cells are mostly characterized by containing solid salts in the path of the current.

If two reacting constituents are present in mutual admixture, the reaction can no longer be treated as "fixed," since osmotic forces then come also into play. But even for such cases suitable galvanic cells for measuring the free energy are described. To these belong, for instance, the formation of salt hydrates, in which it is almost always found that the resulting salt hydrate is considerably soluble in water, and in consequence a fluid mixture of salt hydrate and water enters into the reaction.

Further, new electrometric methods were given for chemical reactions of the kind described, in which the reacting constituents were present diluted by indifferent bodies. To such belong especially such reactions in which salts take part in practically completely dissociated dilute solutions. It could be shown in what way cells could be arranged for the measurement of reactions, avoiding the diffusion potentials, as, for instance, the reactions in the Bredig-Knüpffer cell.

### Railway Track Cell

The paper by **Mr. E. L. Marshall**, of the National Carbon Company, Cleveland, Ohio, described a new cell of the wet type which has been developed within the last ten years for service in railway signalling Its predecessor in the same field was the Daniell gravity cell.

The paper describes the general electrical equipment for automatic block signalling and shows that a cell for the track circuit must fulfil the following requirements: low current on short circuit, constant voltage on closed circuit, large capacity, small fluctuations due to variations in temperature.

The Lalande type of cell was selected to develop a cell of this kind. It is a single-fluid cell with a zinc anode, a cathode of copper oxide and an electrolyte of caustic soda. There had already been perfected a Lalande cell with a low internal resistance and consequently a high amperage on short-circuit. But for the present purpose a high internal resistance was required.

To get a high internal resistance in a Lalande cell use was first made of a perforated porcelain plate placed between the zinc anode and copper oxide cathode. But a more efficient cell was later developed in form of the Columbia track cell. The high internal resistance is obtained in this cell by merely separating the two electrodes a long distance apart in the electrolyte, no added piece being used for the purpose. The construction of the cell is described in some detail and its advantages are pointed out.

### Experiments on White Lead

A paper by **Mr. R. Stuart Owens** gives the results of experiments undertaken to determine in what way and to what extent the character of precipitated white lead is affected by the conditions of precipitation.

Among other experiments the author produced white lead electrolytically on a laboratory scale according to data obtained from the patents of Woltereck and Luckow. The experiments proved that these two electrolytic methods are not run under conditions which give the best precipitate of white lead.

### Electrolytic Iron

A paper by **Dr. Oliver W. Storey**, of the University of Wisconsin, gives the results of a "microscopic study of electrolytic iron," prepared by the refining process of C. F. Burgess. The paper is illustrated by 48 microphotographs.

The results of the study of heated electrolytic iron are summed up as follows:

No change in structure of electrolytic iron could be determined at temperatures below the $A_3$ range.

A fine deposit is more readily changed to the grain structure than a coarse deposit.

With a short heating above the $A_3$ range the fine deposit is transformed into a fine grain structure, while a coarse deposit becomes coarse grained.

The coarse grains resulting from a coarse deposit may be broken down into smaller grains by long annealing at the $Ac_3$ point or by heating to 1000 deg. or higher.

The grain structure resulting from a fine structure is always finer than that resulting from a coarse deposit.

The grains of electrolytic iron do not grow appreciably at 1150 deg.

The microstructure of fused electrolytic iron was next studied and is illustrated by microphotographs.

Rolled electrolytic iron shows the structure of clean furite.

## The Effect of Addition Agents in the Electrodeposition of Iron

A paper by Messrs. **O. P. Watts** and **N. H. Li** gives the results of experiments on various addition agents in the electrodeposition of iron.

Previous experience in refining iron had shown that, while an electrolyte containing only chlorides gave a much smoother deposit than one consisting of the sulphates of iron and ammonia, the iron produced rusted so badly after removal from the electrolyte that a pure chloride electrolyte was not considered practical.

It was found, however, that the admixture of some chloride with the sulphate electrolyte improved the smoothness of the deposit without causing excessive rusting of the iron produced.

The electrolyte chosen as a basis for the addition of various substances consisted of 150 grams crystallized ferrous sulphate ($FeSO_4.7H_2O$) and 75 grams ferrous chloride ($FeCl_2.4H_2O$) per liter, and had a specific gravity of 1.125 at 20 deg. C.

The objectionable features of electrolytic deposits of iron are a roughness which increases with the thickness of the deposit, and a tendency to form vertical grooves or striations. The color of the electrolyte at the end of the test was closely related to the quality of metal produced. A yellowish-green electrolyte almost invariably gave clean metal of a fine color, even though it might be too badly pitted to allow of the practical use of that particular electrolyte. A dark electrolyte fouled by much green precipitate usually yielded very bad-looking metal.

The experiments show that ammonium oxalate and formin are capable of improving upon the smoothness and satisfactory deposits given by the original electrolyte.

**Iron has been produced experimentally** in the electric furnace at the foundry of the Carnegie Institute of Technology, Pittsburgh. The experiments were in charge of Mr. Frederick Crabtree, professor of metallurgy at the Institute. Raw Mesabe iron ore was converted into high-grade pig iron.

**The Senate radium hearing** before the mines and mining committee was attended by practically the same interested parties as appeared before the House committee. No new features were developed. The arguments pro and con were about the same as brought out before. Both hearings have been published and can be secured by those interested.

# Some Economic and Aesthetic Aspects of Electrochemistry*

BY E. F. ROEBER

There is beauty in electrochemistry. The late Ludwig Boltzmann once said that of all artists the mathematical physicist is nearest to the world's Creator in the simplicity, directness and economy of his methods; Boltzmann made this remark in appreciation of the work of Kirchhoff and Maxwell. But we can apply it with equal truth to the electronic theory of our own time which in the simplicity of its fundamental conceptions and in the comprehensiveness of its outlook has all the elements of pure beauty. The intellect which builds the structure of the atoms of the different chemical elements out of a positive electric nucleus in association with varying numbers of negative electrons, and makes his atoms produce the desired result, is a true creator, and his model has beauty like the visible world around us.

But more beauty is hidden in electrochemistry than the mathematical beauty of electrochemical theory. The research electrochemist who works out a new process whether it is the reduction of aluminium from its oxide, or the conversion of amorphous carbon into graphite, or the production of calcium carbide from lime and coke, or whatever else, proceeds exactly along the same methodical lines as the artist, whether he be sculptor or painter or poet. The artist must take nature as it is. But for his work he takes from nature only what his imagination tells him to be essential to the idea he has in mind. It is this selective copying of the essential from nature and this restriction to nothing but the essential that makes a work of art beautiful.

The method is exactly the same with the creative electrochemist. He cannot improve on Nature's processes and methods. All he can do is to imitate or copy Nature's processes and combine them to a certain end. But because his goal is a certain product he can select the starting materials which are essential and use nothing else, and he can select those processes which are essential and combine them into the most direct method of production, and produce only what is wanted. Artificial graphite made in the electric furnace is superior to natural graphite, because nature does not set out to make pure graphite and man can. This makes the economic value of artificial graphite; but it also makes the artificial graphite process, in the bold directness of its execution, a true work of art. Wherever a process is so designed as to reach its object in the most direct way with greatest economy, it is beautiful in the eyes of those who understand its rationale. This is broadly true and not restricted to electrochemistry; but the trained engineer's or scientist's intellectual eye is needed to see this type of beauty.

The thoughts on some particular aspects of electrochemistry which I want to submit to you for reflection tonight are of a cognate nature. They refer to the part which electrochemistry plays in the changes now going on in modern civilization in economic and æsthetic valuations. Our age is called an age of unrest and revolution. Whether we are really so much more restless than our ancestors is open to discussion and hard to decide. But that the scientific and concomitant engineering advances of the last century have brought an entirely new phase (in the phase-rule sense) into the play of human reactions which make up the history of mankind, is not open to question. That the effects of modern science and engineering go far beyond their spheres of immediate interest is undisputed. What then is the effect of electrochemistry on two fields apparently so remote as political economy and æsthetics?

To express the question concisely I borrow Friedrich Nietzsche's phrase of the revaluation of values. My subject is: How does electrochemistry bring about a revaluation of economic and æsthetic values? I have brought Nietzsche's name into this discussion for still another reason. Nietzsche's brilliant and, at first sight, extraordinarily daring attempt of a revaluation of ethical values for the sake of creating the "Uebermensch," is perhaps in the final analysis of its positive aspects nothing more than a robust reassertion of what was strong and healthy in the viewpoints and valuations of classic Greece and Rome, but has been lost in the last nineteen centuries to an exaggerated weak sentimentality. Nietzsche wanted to make restitution of this lost strength and health from classic Greece to modern civilization and thus create a new ethics. Now, it would seem that the effect of science and engineering on æsthetics is acting at present in the same direction in emphasizing the necessity of a return to the æsthetic viewpoint of classic Greece, as embodied in Socrates' view of the kinship of beauty and utility. It is for this reason that before speaking of æsthetic aspects of electrochemistry it is necessary to take up its economic aspects.

How are economic values being created by industrial electrochemistry? For this discussion Professor Karl Knies' old and well-known conception is very useful: that economic value is of three kinds—place value, time value and form value. If I may use the text-book illustration, ice in winter in the Maine woods has no economic value because there is no market for it there. Brought to New York, it gets place value, because there is a demand for it in New York. Stored and sold in summer time, it gets an additional economic value—time value. Nothing has been done to the ice itself by man. The place value has been created by transportation, the time value by storing, and as we will see later these two points are of importance for the production of economic values by electrochemistry.

But for the present let us consider the third kind of economic value—form value—that is the value created by the work done by man on the materials of nature, comprising mechanical work as well as chemical changes. Any chemical reaction produces or annihilates form values, economically speaking. But what is the distinguishing characteristic feature of the form values produced by the electrochemical industries? Let us take a few typical examples.

By the electrolysis of a solution of common salt we get caustic soda and chlorine, and we work up the latter perhaps into bleaching powder. The excess of the value of the caustic soda and bleaching powder over that of common salt is the form value produced by this process. So it is in the production of calcium carbide from lime and coke, of nitric acid and nitrates from atmospheric air and so on.

The fixation of atmospheric nitrogen, representing an extreme case, is most instructive. The raw material is atmospheric air which, as such, has no economic value at all, so that we might say that in the production of nitrate from air the economic efficiency becomes infinitely high. It sounds very well to speak of a process with an infinitely high economic efficiency, but if we stop to remember that exactly this process which is now worked with fair financial results in Norway proved a commercial failure some ten years ago in Niagara Falls, it is evident that our consideration must have been in some way so one-sided as to be misleading.

Why was fixation of atmospheric nitrogen a failure at Niagara Falls and why is it a success in Norway? Not primarily on account of the process, because the Bradley-Lovejoy process worked with about the same technical efficiency as the Birkeland-Eyde process, though the apparatus was considerably more ecomplicated. No, the decisive element which caused failure at Niagara Falls and success in Norway, is the cost of electric power which is three to five times lower in Norway than at Niagara Falls. And this brings us right to the root of the whole matter.

---

*Presidential address delivered before the American Electrochemical Society on April 16, 1914.

In discussing the economic value of some electrochemical products we have so far, in a one-sided way, compared only the value of the starting materials and of the end products; but we have entirely neglected the fact that in these cases we have to do not only with materials as such, but rather with the storage of energy in materials. The form value of many products of electrochemical industries is essentially due to their high energy content. A large amount of chemical energy is stored in electrochemical products; it is latent under ordinary conditions, but it may be gotten out wherever and whenever necessity arises, and this fact makes them useful and economically valuable.

Let us carry this consideration a little further by making use of the conception that the energy of a given system may be considered as the product of two factors —the capacity factor and the intensity factor, to use the terms of Ostwald. The total amount of energy remains the same, however the two factors may be changed, if only their product remains the same. But for the engineering applications it makes an enormous difference whether we make the capacity factor small and the intensity factor large or the former large and the latter small.

In case of a waterfall the amount of water passing over the fall in a certain time is the capacity factor, the height of the fall is the intensity factor. The engineering requirements for the development of a waterfall with little water and a high fall are very different from the case of a lot of water with a small fall, though the energy may be exactly the same in both cases.

In the case of electrical energy the current passing in a certain time, measured in coulombs, is the capacity factor, the pressure in volts is the intensity factor. For electric power transmission we make the intensity factor, the voltage, as large as possible, in order to decrease the transmission loss.

In the case of electrochemical products, the weight of the materials is the capacity foctor, the specific energy stored in them per unit of weight is the intensity factor. If we make the latter high, if we store a lot of energy in a little matter, it will again be favorable in reducing the cost of transportation.

Now the element of transportation brings us to the conception of the place value of electrochemical products. If their form value is due to their high energy content, their place value is due to the possibility of chemical power transmission by material transportation of electrochemical products. Those products of the electrochemical industries which are characterized by a high specific energy content are the principal medium of chemical power transmission.

There are two points of chemical power transmission to be specially emphasized. One is that it is not bound to a fixed route. It requires no line wires. It makes use of the ordinary transportation facilities for materials—railways, ships, etc. This is important, as it opens fields for chemical power transmission where electrical power transmission fails. For instance, there are still very large areas in this country, Canada and elsewhere which are so little populated that it would not pay to erect an electric transmission system to provide electric current for lighting. Here acetylene lighting is of supreme importance. And acetylene lighting is a case of chemical power transmission. At Niagara Falls the electric furnace produces calcium carbide from lime and carbon, and chemical energy is thus stored in the carbide which is transported with its energy to any place where acetylene is required for lighting.

If transportation creates place value, storage creates time value. The use of chemical energy after it has been transmitted is not bound to a certain time and that is the second important feature of chemical power transmission. With electrical energy which cannot be stored as such, it is necessary to use the transmitted energy at once or to provide special means for storing it. In this respect chemical power transmission differs essentially from electric power transmission and is superior to it. Chemical energy is in itself essentially stored latent energy, and is used, therefore, in connection with other systems of power transmission for storage purposes, as in the case of storage batteries for electric power systems. The time value of calcium carbide is due to the fact that we can store it and can produce the acetylene just at the moment when it is needed for lighting.

There is a long list of electrochemical products which may be considered from the viewpoint of chemical power transmission. In bleaching powder we transmit the possibility of producing a bleaching or a disinfecting liquid whenever and wherever it is needed. In the series of peroxides we transmit their avidity to give off an atom of oxygen when and where we want it, or the reaction caused by it.

As pretty and concrete an illustration of chemical power transmission as we may wish is found in Hans Goldschmidt's ingenious aluminothermic reaction. The heat of reaction of aluminium and oxygen in forming alumina is relatively very high per unit of weight of aluminium. This is just the reason why the economical reduction of aluminium from alumina did not succeed until electrolysis was resorted to. Now, the fundamental idea of the aluminothermic method is that we have in metallic aluminium a medium which gives us by combination with oxygen a large amount of energy where-ever or whenever needed. In thermit, the mixturue of aluminium and iron oxide, we transport essentially the capability of producing at any place and at any time highly superheated molten steel for welding rails, for making repairs, and so on.

Again, in the new and important Norwegian nitrate industry we have an example of what we may call international chemical power transmission, as the economical value of Norsk saltpeter depends on its easy transportation by ship to other countries. Thus we have at the same time creation of economic values in Norway by building up a new and important industry, and creation of economic values in other countries by using the Norsk saltpeter to further agriculture.

I have dwelt on the relation of electrochemistry to chemical power transmission at such length because so many electrochemical products can be considered from this viewpoint. But it would be wrong to think that the whole of electrochemistry can thus be viewed. There is quite a number of very important electrochemical products in which with no stretch of imagination I am able to detect the elements of chemical power transmission. But in all such cases the form value is high.

In the case of aluminium we have the aspect of chemical power transmission only in the aluminothermic reaction, which though big in itself, uses only a small amount of the total output of aluminium. In cooking utensils, in line-wire construction and other applications it is simply the mechanical and electrical properties of aluminium which count and which give it a high form value.

In electrolytic copper refining, the oldest and certainly one of the biggest electrochemical industries, the increase of form value is remarkable. It is a double one. First, the gold and silver are recovered; second, the copper itself is considerably increased in form value, due to its greater purity and resulting higher electric conductivity.

All those products of electrochemical industries which have nothing to do with chemical power transmission have a high form value, and must have it, because otherwise it would not pay to use an electrochemical process in view of the high cost of electrical power. Hence, the well-known axiom that in all such applications the use of electrochemical processes should be restricted as much as possible to the finishing touches, that is, to the refining of a comparatively advanced product.

In addressing the American Electrochemical Society I need hardly show at length how this creation of economic values by the electrochemical industries has affected and is affecting modern civilization in its various phases. What was waste before and what was considered a nuisance, becomes valuable. When the early Colorado gold seekers discovered tungsten ore in Boulder county they cursed it as it was not what they wanted. From their cursed "heavy black sand" electrochemistry has given to civilization ferro-tungsten and the tungsten lamp. From culm, the waste material of the anthracite coal mines Acheson has given to the world artificial graphite with its immense applications. Then there are the grand electric-furnace industries of artificial abrasives in use in so many walks of life. And so I could go on through the list of electrochemical products down to Cottrell's electrostatic process of recovering values from obnoxious smelter fumes. Only this, however, I should add, that electrolytic copper refining, itself made possible by the dynamo, has paid back its debt to electrical engineering, and by furnishing high-conductivity copper has made modern electric power transmission possible. And as we have seen, in chemical power transmission electrochemistry has brought into modern civilization an absolutely new element by which what is now waste power is being scattered all over the world to build up industries, to further agriculture with fertilizers, to light cities with acetylene, to aid public health with bleaching powder, and to affect civilization in general in its most heterogeneous aspects. That electrochemists as true creators are bringing about a revaluation of economic values there can be no doubt. But what has electrochemistry to do with æsthetics?

If beauty is perceived through our senses, the first question is: How has modern engineering affected our senses? And the answer is simply that modern engineering has given us artificial senses in addition to our natural senses. In the old days when the few pieces of apparatus in physical and chemical laboratories were home-made affairs, it was said that experimental physicists and chemists should be able to see with their ears and hear by touch, smell with their tongues and measure temperatures with their eyes. Now modern engineering has given us instruments and apparatus which really represent new senses and which are available to a much more general public. And what is more, our artificial senses can be repaired or replaced by new and better ones and they give us permanent records.

I am not stretching the meaning of the term senses in speaking of instruments as artificial senses. To the electrical engineer the readings of the voltmeter and wattmeter are as real and as true indications of the outside world as though he put his head out of the window to feel whence the wind blows. Pyrometers give as real, though much more exact indications of temperature, as the touch by hand of a hot body or the trained eye of the furnace man. The photographic camera is a new artificial eye that preserves the record of what it sees. Successive photographs put together in a moving-picture enable us to crowd into a period of five minutes what may have happened in a year. We can see crystals grow and plants grow. The electric oscillograph gives us a record that permits us to see at leisure transient phenomena that happen in portions of a second and study over them for hours. The telephone stretches the ability of the human ear so that it can hear in Denver what is said in New York. And if we hear our children of three or four years talk to us over the long-distance telephone in such a self-evident, matter-of-fact way as though they were sitting on our knees, we cannot escape the conclusion that a new generation is rising to which the perception of the outside world comes through new senses, and which consequently looks at the world with new eyes. What has electrochemistry to offer to this new generation in æsthetic ideals?

It seems to me that the fundamental contribution which electrochemistry has to make to æsthetics is to carry to its last consequence the principle that waste can never be beautiful. Of course, this principle is as old as art. Waste of words in a work of literature, waste of lines or colors in pictures, waste of space in architecture, have always been considered the opposite of beautiful. But the growing multiplicity of our sensual knowledge, due to the magnified and projected extension of our senses, forces us to see waste where our ancestors saw beauty and had a right to see beauty.

Permit me to concentrate my remarks on the one subject that is uppermost in this connection in the minds of American electrochemists—the question of the power development of Niagara Falls. I use it as a clear-cut example of what is meant by revaluation of æsthetic values by electrochemistry. The magnificent group of electrochemical industries of Niagara Falls, which are the pride of every American electrochemist and should be the pride of the whole American nation, suffers seriously from the power famine due to the cessation of power development by international agreement between the United States and Canada. This agreement is based on the alleged will of the people of both countries to have the falls preserved as a scenic spectacle on the principle of conservation of natural beauty. The battle cry is conservation of natural beauty for the people.

The counter-argument has been made that the natural-beauty conservationists want to conserve something that no longer exists. With this I agree, but I hesitate to agree with the expression usually given to this argument, namely, that if Niagara Falls could be preserved in its original magnificence, it would be worth while, but that Niagara as a majestic spectacle has never belonged to the present generation, that its beauty had been given up to noisy and offensive exploitation long before the first power station was erected.

This may be true, but it seems to me that this argument does not reach the root of the matter. The beauty of Niagara Falls, like all beauty, is subjective in the onlooker. The question is simply: What do we see when we stand at the brink of Niagara Falls?

Our ancestors who knew nothing of the principle of conservation of energy, of transformation of different forms of energy into each other, looked simply at the material side of the Falls and saw beauty and had a right to see beauty. And if we force ourselves into such a one-sided attitude of mind we can still see beauty.

But if we stand as modern men at the Falls with a free attitude of mind, we don't see simply water, we see power. We see the possibilities of using this power for electric power transmission for lighting, traction and industrial purposes on a wider area. We see the even greater possibility of storing this power in electrochemical products and utilizing them all over the land in all walks of life. If we look at the Falls with this attitude of mind which is the natural one for us, every cubic foot of water that goes thundering over the falls unutilized appeals to us as waste and nothing but waste.

Now waste can never be beautiful. If the artist's selection of the essential and nothing but the essential makes a work of art beautiful, anything that strikes our imagination as waste must prevent æsthetic enjoyment. If we could look at Niagara Falls with the eyes of our ancestors it would be different; but in full possession of our extended senses which an engineering age has given us, the Falls of Niagara—as much of them as is not utilized—must simply impress us as a waste of immense proportions.

And the very element of bigness which was an element of beauty to our ancestors, has necessarily become to us the reverse, emphasizing only more emphatically the criminal negligence of letting waste on such a tremendous scale go on. Undeveloped Niagara Falls remains spectacular even to the modern man, but it is no longer beautiful.

The perverse mind of Nero could enjoy the spectacle of Rome burning. Children and fools might naively delight in a conflagration that would consume for spectacular purposes a million tons of coal a week. We let the equivalent waste go on in waterpower and hear it called saving beauty for the people.

But there is little use in arguing in æsthetic matters. All we can really do is to make people see for themselves, use their own senses, all of them, their natural ones and their artificial ones. This is what engineering development tends to do every day; and we can rest assured that, as certainly as day follows night, a new generation is rising that will use its senses, all of them, and make its own æsthetics and enforce it.

And when that time has come and people look at the Falls of Niagara running dry their imagination will reveal to them immense beauty, health, wealth scattered by electrical and chemical means all over the country, while the grandeur of the whirlpool rapids, unchanged and undiminished will have a higher æsthetic value, a deeper meaning of beauty than it can possibly have for us. The world will then smile at the æsthetic scruples of so many well-meaning people of our own time and will wonder what all that talk of saving Nature's beauty was about.

---

**The Diesel Engine** is the title of an artistic, 112-page pamphlet, issued by the Busch-Sulzer Bros.—Diesel Engine Company, St. Louis, Mo. The catalog contains notes on the efficiency, economy, life, construction, operation and fuel of the Diesel engine, and gives illustrations of Diesel plants in 21 states.

**Silent Chain Drives.**—For the first time an engineering data book has been published by a manufacturing concern which will enable users of power to select the correct silent-chain drives for their work and determine exact costs from list prices shown in the book. Besides giving complete engineering information on silent-chain driving in simple and compact form, Data Book No. 125 describes many uses of silent chain for the efficient transmission of power and gives specific reasons and illustrations showing application in a large variety of uses. Link-belt silent chain is a series of links connected by joints which consist of segmental case-hardened bushings and case-hardened steel pins. The chain is as flexible as a leather belt—as positive as a gear. Its rated efficiency is 98.2 per cent on actual test. It will transmit any amount of power quietly. Over 200,000 installations were drawn upon for the information contained in this data book. The book is the only work of its kind. Copies can be obtained free of charge from the Link-Belt Company, Thirty-ninth Street and Stewart Avenue, Chicago, Ill.

## Celebration of School of Mines, Columbia University

Dr. Leo H. Baekeland will be the first lecturer in the Chandler Foundation on the afternoon of May 29 at Columbia University, during the celebration of the fiftieth anniversary of the founding of the School of Mines.

The celebration of the School of Mines begins on the evening of May 28 with a reception in the gymnasium, followed by a dance. On the morning of May 29 there will be a meeting in the gymnasium, at which eminent engineers will speak and honorary degrees will be given to graduates. An alumni luncheon will follow, and the Chandler lecture will be given in the afternoon, the celebration closing with the banquet at the Waldorf-Astoria in the evening.

## Personal

Mr. **Paul O. Abbe** has moved his New York office from Room 1203, Johnston Bldg., to Rooms 916-20, of the same building, where he will have larger quarters. Mr. Abbe has recently been made president of the Efficiency Engineering Company, 30 Broad Street, New York City.

Mr. **H. W. Hardinge**, president of the Hardinge Conical Mill Company, has returned to New York City from a two months' trip through the Western mining districts.

**Professor E. Heyn**, of Berlin, Germany, will deliver the annual May lecture before the Institute of Metals, London. Professor Heyn's subject will be "Internal Strains in Cold-Wrought Metals and Some Troubles Caused Thereby."

Mr. **Henry E. Jacoby** has recently concluded arrangements to act as the Eastern representative of the Vulcan Copper Works Company, of Cincinnati, Ohio, manufacturers of copper apparatus for industrial chemical purposes. Mr. Jacoby's offices are at 95 Liberty Street, New York City.

Mr. **Robert M. Keeney**, has resigned his position as electrometallurgist in the Bureau of Mines, to take effect April 30. He will go to Cornucopia, Ore., where he will have charge of the construction of a 100-ton cyanide plant, tramway and power house for the Baker Mines Co.

Mr. **Albert S. Knight**, of the International Acheson Graphite Co., is now in Europe on a business trip. During the next few months mail addressed to him in care of E. G. Acheson, Ltd., 5 Chancery Lane, London, will be promptly forwarded.

Mr. **William D. Mainwaring**, who for the past eleven years was connected with the Detroit plant of the Railway Steel Spring Co., as chemist and metallurgical engineer, has opened a consulting business at 866-868-870 Rockefeller Bldg., Cleveland, Ohio, as a production engineer. Mr. Mainwaring was formerly connected with the open-hearth department of the Pencoyd plant of the American Bridge Company, during the installation of the continuous process of the manufacture of steel. All the furnace records of his father, Isaac Mainwaring, who worked out the practical details as to furnaces and process at Chattanooga, Pencoyd and later in England, have recently come into his possession. He now has a continuous record of the progress of steel manufacture from 1891 to the present date.

Mr. **Wm. Acheson Smith**, general manager of the International Acheson Graphite Company, returned from a flying trip to Europe in time to attend the meeting of the American Electrochemical Society on the last day.

## Synopsis of Chemical and Metallurgical Literature

### Gold and Silver

**Nipissing Metallurgical Practice.**—The principal new features of the cyanide practice in the low-grade mill of the Nipissing Mining Co., Ltd., Cobalt, Canada, are a wet desulphurizing process to break up refractory silver minerals, and the substitution of aluminium dust for zinc as a precipitant. These and other details of Nipissing practice are given in a paper by **Mr. James Johnston,** published in the January "Bulletin" of the American Institute of Mining Engineers.

On the completion of the company's mill for high-grade ore, where a combination of amalgamation and cyaniding effects a total recovery of 99 per cent from 2500-oz. silver ore, investigations were begun on the best method of treating the low-grade material. Concentration and cyaniding were considered, the former producing a smelting product and the latter silver bullion 999 fine. The estimates of the two plans were as follows:

Comparison of Mills Treating 200 Tons per Day

| | |
|---|---|
| Commercial assay of ore........ | 30.99 oz. |
| Correction on pulp.............. | 1.10 " |
| Corrected assay ............ | 32.09 oz. |

| | | |
|---|---|---|
| Cyanide mill to yield 90% extraction. Approximate cost, $250,000. ........ | | |
| 90% x 32.09 oz. = 28.88 oz. at 52c., plus 3/10c. increase price in marketing .......... | | $15.16 |
| Working cost .......... | $3.00 | |
| Express on bullion, $3.50 per cwt. = 23c. per oz. on 28.88 oz. .......... | 0.07 | 3.07 |
| Profit per ton .......... | | $12.09 |
| Concentration mill to yield 80% extraction. Approximate cost, $160,000.......... | | |
| 80% x 32.09 oz. = 25.67 oz. at 52c.......... | | $13.35 |
| Working cost .......... | $1.25 | |
| Marketing concentrates, 10% .......... | 1.33 | |
| Difference between corrected and commercial assay on concentrates, 2% .......... | 0.27 | 2.85 |
| Profit per ton .......... | | $10.50 |
| Profit per ton, in favor of cyanide mill.......... | | $1.59 |

The actual results obtained in the cyanide mill finally constructed are as follows:

| | |
|---|---|
| Cost of construction............. | $254,839 |
| Extraction on a 26-oz. ore, per cent. | 92 to 93 |
| Working cost, per ton, less than... | $3.00 |
| Tonnage daily treated............ | 244 |

The following are representative costs for the concrete construction of battery foundation and walls for the building and ore bins.

| | |
|---|---|
| Battery block...... | 846 cu. yd. concrete |
| Building and walls. | 349 " " |
| Total .......... | 1195 " " using 945 bbl. cement |

| | | |
|---|---|---|
| Labor ................ | $2,669.48 | |
| Supplies ............... | 3,735.33 | |
| Lumber ................ | 246.57 | |
| Carpenter shop labor.... | 790.86 | |
| Machine shop labor..... | 87.78 | |
| Teaming ............... | 139.34 | |
| Fuel .................. | 12.85 | |
| Air for operating machinery .............. | 400.00 | |
| Total ................ | $8,082.21 | = $6.76 per cu. yd. |

Retaining walls and sundry small walls and foundations on the tank-floor level comprised 434 cu. yd., using 485 bbl. cement, and cost $13.09 per cubic yard.

The original estimated cost for the cyanide mill was $250,000. Following is the actual cost of construction, exclusive of the tram lines, washing plant, etc., which would have been common to either a cyanide or concentrating mill.

Cost of Construction of Low-Grade Mill.
To January 31, 1913

| | |
|---|---|
| Store and office buildings............... | $725.65 |
| Proportion office and supervision........ | 6,652.97 |
| Excavations .......................... | 29,728.30 |
| Foundations .......................... | 20,159.39 |
| Buildings over mill.................... | 24,618.99 |
| Battery equipment .................... | 24,241.42 |
| Proportion electrical equipment for above. | 5,267.38 |
| Tube mills and classifiers.............. | 23,223.80 |
| Proportion electrical equipment for above. | 12,091.02 |
| Slime treatment and storage............ | 31,519.84 |
| Proportion electrical equipment for above. | 4,477.26 |
| Cyanide filter plant................... | 14,154.92 |
| Proportion electrical equipment for above. | 3,040.71 |
| Piping, pumps, etc..................... | 12,886.19 |
| Precipitation ......................... | 9,989.23 |
| Proportion electrical equipment for above. | 239.42 |
| Heating plant ......................... | 12,333.70 |
| Water Service ......................... | 5,288.57 |
| Proportion electrical equipment for above. | 1,028.13 |
| | $241,666.89 |
| Additional cost for intermediate filtering and desulphurizing equipment not originally included ...................... | 13,172.63 |
| Total cost of mill.................. | $254,839.52 |

Briefly the mill practice is as follows: The ore is crushed to 3-in. in gyratory crushers and sent to the washing plant, where it is hand-picked and jigged. The high-grade material thus recovered is sent to the high-grade mill. The low-grade discard from the washing plant is crushed in stamp battery and tube mills in a caustic soda solution, producing a slime which is desulphurized in tube mill and vats containing aluminium. The slime is dewatered and transferred to vats for cyanide treatment, filtered and discharged to the dump. The cyanide solution is precipitated by aluminum dust, and the precipitate is melted and refined to silver bullion 999 fine.

The importance of extremely fine grinding was demonstrated in early experiments. It was considered that all the ore, silver included, should be ground to pass a 200-mesh screen, and then this product classified to take out the minus 200-mesh sand for regrinding, so that only about 15 to 20 per cent of sand, much finer than minus 200-mesh, would remain in the product delivered to the cyanide plant. As an example of the necessity of fine grinding, it is shown that when the pulp delivered to the cyanide plant contained 3 to 4 per cent plus 200-mesh and 30 to 35 per cent sand in minus 200-mesh, the residue after cyaniding will contain from 3.5 to 5 oz. silver per ton. When a grading test shows 0.5 to 1 per cent plus 200-mesh and from 15 to 20 per cent sand in the minus 200-mesh, the residue after cyaniding will contain less than 2 oz. silver per ton.

The wet desulphurizing process used to decompose the silver minerals was initiated by Mr. J. J. Denny. It rests on the fact that the refractory silver minerals are broken up when the slime pulp is brought in contact with aluminium in a caustic soda solution, leaving the silver in a spongy, metallic state readily amenable to cyaniding. This process is carried out by passing the slime through a revolving tube mill in which is a charge of 4000 lb. aluminium in cubes about 1½ or 2 in. After this agitation a further treatment is given in vats lined with aluminium plates, where the pulp is slowly agitated. This treatment reduces the time of treatment from 120 to 48 hours, and yields a better extraction by 1 to 4 oz. silver per ton. The slime thus treated is filtered before transfer to cyanide vats, where it is treated for 48 to 60 hours by air and mechanical agitation. This treated slime is filtered in a Butters plant, and the solution is precipitated with aluminium dust.

The practical benefits gained by aluminium precipitation are: No fouling of mill solution; more active solution; a regeneration of 0.608 lb. cyanide per ton of solution treated, equivalent to 1.67 lb. cyanide per ton of ore, or 408 lb. per day; recovery of silver precipitate averaging 27,000 oz. per ton, or about 93 per cent silver. The operating cost per ton of ore treated for July, August and September, 1913, calculated on the basis of 7320 tons per month, was $2.952.

**The Dome Mill, Porcupine, Ontario, Canada.**—Among the interesting papers presented at the annual meeting of the Canadian Mining Institute in 1913 was one on the cyanidation of gold ore at the Dome mine, by **Mr. D. L. H. Forbes.** Dome ore consists of quartz and schisted slate, heavily mineralized with pyrite. When ground it yields a small proportion of colloids, so that the pulp is ideal for settling and filtration under pressure. The gold generally occurs finely divided.

After crushing in gyratory and jaw crushers, the ore is fed to 1200-lb. stamps dropping 6½ in. at the rate of 102 drops per min. Ten-mesh rolled slotted wire screen is used, but tests have been made on other screens to determine the effect on stamp duty, as shown below.

*Effect of Screen Opening on Stamp Duty and Product*

| Mesh | Tons per stamp per day | Screen tests on battery discharge | | | |
|---|---|---|---|---|---|
| | | +60 mesh per cent | +100 mesh per cent | +200 mesh per cent | —200 mesh per cent |
| 16 | 6.8 | 41.6 | 8.8 | 10.4 | 38.8 |
| 14 | 7.9 | 62.0 | 6.4 | 6.8 | 24.8 |
| 12 | 9.0 | 64.0 | 7.0 | 6.0 | 22.8 |
| 10 | 9.6 | 59.0 | 15.0 | 7.0 | 19.0 |

When the mill was started there were primary amalgamating plates in front of the stamps, but with the coarse crushing finally adopted these were abandoned on account of the scouring action of the coarse sand. The relation of the screen used to recovery by amalgamation was as follows:

| Mesh of Screens used | Percentage recovery by amalgamation |
|---|---|
| 16 | 78 |
| 14 | 75 |
| 12 | 55 |
| 10 | 46 to 50 |

Following the stamps, the pulp is classified into sand and slime, the former being ground in tube mills and returned to the classifiers. The slime is passed over amalgamating plates, which recover from 46 to 50 per cent of the total gold, and thence through classifying cones to recover any coarse gold, amalgam, etc., which is returned to the tube mills. The most economical results are obtained when the slime is ground so that 75 per cent will pass a 200-mesh screen.

The slime leaving the classifiers contains 10 tons of water to 1 of solids. It is thickened in Dorr thickeners to a consistency of 44 per cent moisture. Cyanide is added to the thickened pulp in sufficient quantity to give a solution strength of 1 lb. per ton. The pulp is then agitated in a continuous Pachuca tank system, by means of compressed air at 20 lb. per sq. in. at the receiver. From the final treatment tank the pulp is run to a storage tank, where it is agitated and drawn off intermittently for filtration in Merrill presses. About 20 tons of slime at a dilution of 1.1 is drawn at each charge, filtered, washed with precipitated solution and discharged. A perceptible extraction of undissolved gold takes place during washing. The discharged pulp is again thickened for recovery of water.

The Merrill system of zinc-dust precipitation is used. The value of solution varies from $2.50 to $6 per ton. The precipitate has a value of about $40 per lb. The solution flowing from the press contains from a trace to 8 cents per ton in gold.

The method of preparing the zinc-dust emulsion is to grind the dust with solution in a small tube mill, and feed the discharge in definite amount at a uniform rate to the pregnant solution at the suction side of the pumps. The average consumption of zinc per ton of ore treated is about 0.37 lb.

Gold from retorted amalgam is melted into bars of 990 to 995 total fineness, of which about 100 is silver. The precipitate from the cyanide department is treated with acid, dried, fluxed, briquetted and smelted in a lead furnace. The resulting bullion is cupelled. The slag assays from $40 to $100 per ton, and is retreated later with cupel crusts, etc., whereupon the slag contains only about $3 per ton gold. Cupellation is carried to a point where the metal carries about 0.025 of lead. This metal easily breaks when cool, and is then charged into the tilting furnace, melted and cast into bars. The fineness of this bullion is 990.

Mill operations are controlled by assays of samples taken (1) at the battery pin, (2) at the discharge from batteries, (3) slime leaving amalgamation plates, (4) filter press residues, (5) sluicing water sent to waste with residues, (6) pregnant and barren solutions. Calculated heads, from gold recovered plus gold lost divided by tonnage, agree well with the average of battery samples, but do not check well with battery bin samples. Tonnage is calculated from samples of slime flowing from the tube mill circuit to the thickening tanks. As this pulp contains 10 parts water to 1 part of ore, errors are divided by 10 when referred to dry pulp.

The metallurgical extraction on half-ounce ore is over 95 per cent, divided approximately half and half between amalgamation and cyanidation.

**Cyanidation of Silver Sulphide Ore.**—The ore in the Ocampo district, Mexico, is practically all argentite, $Ag_2S$, with some associated gold. The ratio of silver to gold in the ore is about 60.1. The silver mineral occurs usually finely divided, but can sometimes be seen with the naked eye. Something of the history of the metallurgy of this ore, and the projected modern mill for its present treatment is told by **Mr. Robert Linton** in the February Bulletin of the A. I. M. E.

Six mills formerly were operated on the mines now owned by the Sierra Consolidated Mines Co., in the Ocampo district. Until about seven years ago the treatment consisted in plate amalgamation, followed by concentration with pan-amalgamation of the concentrates. Records show recoveries of from 62 to 79 per cent of the gold and from 46 to 64 per cent of the silver. The milling costs ranged from $3.25 to $5.01 per ton.

The first cyanide mill in Ocampo was installed in 1906. It comprised rock breakers, stamps, Wilfley tables, leaching vats for sand, Pachuca agitators for slime, clarifying filter press, zinc boxes and accessory equipment. Concentrates were ground in strong cyanide solution. Sand treatment required from 20 to 25 days, and slime treatment 8 to 10 days. The recovery was about 70 per cent for both metals, and cyanide consumption was more than 5 lb. per ton of ore. Milling cost averaged about $5 per ton.

Tests made under the present management indicated that sand leaching could be eliminated entirely, for better extraction could be made from slime. Where 80 per cent of the silver could be extracted from slime in 20 hours' agitation with strong solution, the extraction from sand at the end of 18 days rarely reached 75 per cent. Fine grinding is required to expose the silver to the dissolving action of cyanide; the more nearly a fineness of 200-mesh is approached the better is the extraction. The most favorable strength of cyanide solution is 0.32 per cent KCN, and at this strength extractions of 84 to 89 per cent of the silver and 93 to 95 per cent of the gold can be obtained in agitations of 34 hr. duration. Chemical consumption of cyanide is 1.4 lb. and of lime 12 lb. per ton of ore treated. Mechanical losses probably will bring these figures up to 2.5 lb. and 15 to 20 lb., respectively. Protective alkalinity should be maintained during agitation at 0.08. Lead acetate was found to be of no value in the treatment.

Tests on cyaniding concentrates showed the best results by grinding in 0.2 per cent KCN solution and agitating in 0.6 per cent solution, which was raised to 0.8 per cent toward the end of the treatment. Protective alkalinity maintained at 0.10. Lead acetate did not benefit extraction, but a small amount aided in keeping solutions clear. Concentration is not indicated in treating ordinary grades of this ore, though it might be valuable in handling rich ore.

A new mill, which had been designed on these tests, was under construction when work ceased on account of unsettled conditions in Mexico. The equipment will comprise rock breakers, 1500-lb. stamps, tube mills, Esperanza-type classifier, Dorr thickeners, Pachuca agitators, Oliver continuous filter, zinc boxes and accessory equipment.

The coarse breakers will reduce the ore to 2-in. size. This product will be screened over a 3/16-in. screen, and the undersize will by-pass the stamps, running to the classifiers. The latter will receive the battery pulp also and will deliver sand to tube mills arranged in closed circuit with the classifier. Agitators will be arranged in series for continuous agitation, giving a total time of 55 hr. in the tanks. The solution from the Oliver filter and from the overflow of the thickener preceding it will be clarified and precipitated. The mill has been designed in units, with a view to future enlargement.

### Lead and Zinc

**Selective Flotation by Horwood's Process.**—The Broken Hill correspondent of the Australian Mining Standard, Jan. 15, 1914, states that the successful establishment of the Horwood process of selective flotation at the works of the Zinc Corporation was one of the metallurgical achievements of 1913. The principle of this process is the roasting of mixed lead-zinc concentrates obtained by flotation, whereby the lead particles are slightly sulphatized while the zinc is unaffected. On floating the roasted product the zinc alone floats and the lead remains submerged.

A plant having a capacity of 500 tons weekly has been in operation for over six months, treating current and accumulated slime concentrates. The slimes are first dewatered and washed to remove soluble salts, then lightly roasted in an Edwards furnace, and finally treated again by flotation. Typical actual results from this plant are as follows:

| | Zinc, per cent | Lead, per cent | Silver, oz. per ton |
|---|---|---|---|
| Feed to roaster | 40.1 | 14.6 | 21.4 |
| Zinc concentrate | 48.7 | 5.2 | 11.6 |
| Lead residue | 10.2 | 44.2 | 54.6 |

The grade of the lead is, of course, dependent on the amount of gangue in the feed.

Tests made on Tasmanian ores show that 85 to 90 per cent of the zinc can be recovered as a concentrate assaying 57 to 58 per cent zinc, while the lead will remain with the iron content of the ore. From 75 to 80 per cent of the silver content of the ore and about 90 per cent of the gold will accompany the lead residue.

### Tin

**Assay of Tin Ores and Concentrates.**—In Bulletin No. 113, Institution of Mining and Metallurgy, will be found two papers bearing on methods of analysis of tin ores and concentrates. The first, by Mr. **H. W. Hutchin**, calls attention to the reaction occurring between tin ores and calcium carbonate, when a finely divided mixture is heated under proper conditions. The effect apparently is the formation of calcium stannate, which is readily soluble in hydrochloric acid. This solution can be reduced with nickel and titrated with iodine solution. The author presents many comparisons between Beringer's method and the lime modification, and shows results agreeing very closely. The operation may not be carried out successfully in the ordinary muffle furnace, but it is accomplished in the "tin furnace" described by Beringer in his Text Book of Assaying, or in an apparatus described by the author. Apparently the products of combustion play an important part, and must have access to the charge in the crucible. Alundum crucibles are preferred, but porcelain does well.

The apparatus suggested by the author is as follows: A piece of asbestos mill board, 6 in. in diameter and 1½ in. thick, is perforated in the center with a hole 2¼ in. in diameter. Three iron wire nails 5 in. long are inserted through the board from three equidistant points on the circumference and at a distance of about ⅜ in. from the base. The points of the nails may be covered with asbestos to prevent their oxidation, and the nails can be adjusted to support crucibles of different sizes. A Bunsen burner of large size, ⅝ in. diameter of tube, is used to supply the necessary heat. The crucible to be heated is suspended on the nail points in such a manner that the lower portion is below the board, and the upper portion affected only by radiation from the board. The cone of the flame should envelop the crucible. A large Techlu burner may be used. A charge consists of approximately equal parts of tin ore and calcium oxide, intimately mixed. The lime may be in excess. The reaction is complete in 20 min., with a Bunsen burner, and in 15 min. with a Techlu burner if an alundum crucible is used, or 20 min. with a porcelain crucible. The crucible is covered during the operation. After ignition the charge is brushed out of the crucible, dissolved in hydrochloric acid, reduced with nickel, and titrated with iodine solution.

The second paper on the same subject is by Messrs. **E. A. Wraight** and **P. Litherland Teed**, and consists in an investigation of the Pearce-Low method. In brief this method consists in fusing the finely powdered ore with several times its weight of sodium peroxide in an iron or nickel crucible, dissolving the fusion in hydrochloric acid, reducing with nickel and titrating with iodine solution. The authors investigate the effect of various elements which may be present in ores, and consider various other features of the method.

They conclude (1) that the ore should be ground to at least 100-mesh; (2) that nickel crucibles are superior to iron, as the latter may yield high results by contributing some ferrous chloride in the final titrating solution; (3) the amount of hydrochloric acid in the solution at the time of reduction should be 125 cc., and the bulk of solution should be about 400 cc.; (4) the temperature at titration should be not more than 70° F.; (5) the strength of the standard solution should not be more than 11 g. of iodine and 20 g. potassium iodide in one litre; (6) before titration the calcite that has been added to give a neutral atmosphere should all be dissolved; (7) titanium, tungsten and bismuth interfere seriously and should be removed; titanium by fusion with potassium bisulphate, solution of the fused mass with sulphuric acid and filtration, catching the tin on the filtrate; tungsten also may be removed in a similar manner, or it may be removed by filtration after reduction of the tin solution by nickel; bismuth may be removed at the same time as tungsten, by filtration of the solution after reduction with nickel; (8) nickel should always be used for reduction in preference to iron; (9) in rich ores, zinc, lead, iron, nickel, arsenic, chromium, copper, manganese, uranium, calcium, aluminium, sulphur, fluorine, boron and phosphorus do not interfere.

## Recent Chemical and Metallurgical Patents

### Iron and Steel

**Use of Raw Fuel in Blast Furnaces.**—Carbonized fuel such as coke and charcoal is generally employed in all kinds of blast furnaces. The use of raw or uncarbonized fuels has been attempted, but is accompanied with some difficulties, arising from the fact that the carbonization is not effected where most needed. The object of an invention by **Francois Prudhomme** of Vienne, France, is a device for shaft furnaces of all kinds making it possible to use raw fuels in such furnaces. In fact the furnace becomes an apparatus for carbonizing the raw fuel in the upper half and utilizing this fuel in the smelting operation in a lower zone.

Referring to Fig. 1, which is a vertical sectional elevation of a shaft furnace, the device is seen to consist in a number of superposed rings B provided with inclined tuyeres C entering the wall of the furnace and passing through it. These tuyeres and rings are connected through D with the air supply at E. The introduction of air through the tuyeres results in burning sufficient gases to carbonize the raw fuel, which subsequently reaches the level of the boshes at a relatively high temperature.

The advantages claimed by the inventor are the elimination of expense necessitated by separate carbonization; the use of the heat of the carbonized fuel, and the collection at the outlet of the shaft furnace of certain by-products. (1,092,168, April 7, 1914.)

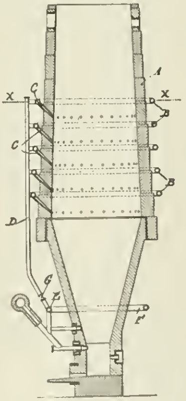

FIG. 1—BLAST FURNACE FOR UNCARBONIZED FUEL

**Air-Cooled Blast Furnace Stack.** — The cooling of thin-walled blast furnaces has usually been accomplished with water circulating through coiled pipes. Objections to this system of cooling are found in the consumption of water, the power required to force the water to the top of the stack, the loss of heat absorbed by the water, and the inability to rapidly control the cooling effect. Mr. **John J. Shannon** of Birmingham, Ala., proposes to utilize air as a cooling medium, particularly in that portion of the furnace above the bosh and crucible. Air is caused to pass through ducts formed by pipes cast in the metal stack-plates, either by a natural draft or forced draft. The cooling system may be so connected with the furnace stoves that the heat absorbed by the air when cooling the stack may be conserved. By this system the air flowing upwardly through the ducts exerts its maximum cooling where most needed, namely, at the bottom of the stack, and tends to radiate heat into the cooler top of the stack and thus maintain more uniform temperature conditions throughout the furnace walls. (1,090,574, March 17, 1914.)

**Welding Powder for Iron and Steel.**—According to a patent granted to Mr. **E. Ernst Eisengraber**, of Frankfort-on-the-Main, Germany, the following compositon forms a good welding powder:

| | |
|---|---|
| Red hematite................. | 70 per cent |
| Coal......................... | 22 " " |
| Flux......................... | 8 " " |

The flux used is sodium phosphate which favors the production of slag. Other fluxes such as fluorspar, cryolite and the like may be used. The welding powder is convenient for welding soft and hard steel and different kinds of steel and iron. (1,091,312, March 24, 1914.)

### Gold and Silver

**Aluminium-Precipitation of Cyanide Solution.**—The use of aluminium as a precipitant for gold and silver is not new. The metal is usually used in the form of dust, but as this method is open to some objections Mr. **Charles Butters** of Oakland, Cal., has proposed the use of aluminium in granulated or solid form. His process is carried out by passing the cyanide solution through a revolving tube mill containing a charge of aluminium in the form of small irregular bodies. The tumbling of the aluminium in the mill causes the abrasion of small particles and prevents the accumulation of gold and silver precipitated on the surface of the aluminium. The out-flowing solution which carries most of the gold and silver in suspension may be sent to a filter press for the recovery of the precious metals. (1,092,765, April 7, 1914.)

**Granulated Zinc Precipitation of Cyanide Solution.**—Zinc is used in two forms for the precipitation of gold and silver from cyanide solutions: dust and shavings. Both methods are open to certain objections which Mr. **Charles H. Urquhart** of Newark, N. J., proposes to overcome by using granulated zinc in a tube mill or other revolving drum through which cyanide solution is caused to flow. The granulated zinc is prepared by pouring molten zinc from a height of two or three feet into cold water. The product consists of small, irregular, unoxidized masses of brittle zinc which, when tumbled in the tube mill, break up into still smaller particles favorable for precipitating purposes. The inventor's apparatus is so arranged that the tube mill is at all times filled with cyanide solution so that no air is present. The outflowing solution carrying the precious metals in suspension is passed through a filter press or other suitable means of recovering the gold and silver. (1,090,661, March 17, 1914.)

### Zinc

**Isherwood Process for Refractory Zinc-Lead Ores.**—According to the patented process of Mr. **Percy C. C. Isherwood** of Bushey Heath, England, refractory zinc-lead ores are treated for the recovery of the zinc by roasting, leaching with sulphuric acid, and electrolyzing the zinc sulphate solution. The ore is first roasted under conditions which will yield both zinc sulphate and oxide, with no sulphide remaining. The leaching is carried out in two stages. First, in an open vat with a quantity of solvent less than that necessary for the solution of all the zinc in the ore; second, in a special form of extractor under pressure with an excess of the solvent. The extractor has been described in this journal, January, 1913, p. 54. The liquor obtained from the extractor is used as the leaching liquor for the first leach of a new quantity of ore. The ore remaining after the complete treatment may be treated for the recovery of any other metals contained. (1,089,412, March 10, 1914.)

**Magnetized Roasted Zinc and Iron Ores.**—A common method of separating iron and zinc minerals is to roast the ore to render iron magnetic and then subject the ore to magnetic treatment whereby the iron is removed. Owing to the fact that zinc minerals frequently carry combined iron, the magnetic gap between the iron ore and the iron-bearing zinc ore is not as wide as can be desired. In order to increase this gap and make it easier to separate iron and zinc minerals by magnetic separation Mr. **Geo. S. Brooks** of DePue, Ill., has patented a method of treating the ore after it has been roasted and prior to magnetic separation. In brief the process consists in subjecting the ore to the action of producer gas. The chief reaction may be expressed by the following:

$$3Fe_2O_3 + CO = 2Fe_3O_4 + CO_2.$$

The apparatus for carrying out this process is shown in Fig. 2. It consists of a long U-shaped chamber having a slope in the direction of its length. It is provided with a feed hopper C and discharge hopper *d*. Explosion doors are provided along the roof of the chamber. Producer gas is admitted through the flue D and the waste products escape at the opposite end through *m*. The hot, roasted ore passes through the chamber and is gradually elevated and dropped through the gas by slowly revolving cups *v* which are keyed on the central shaft. (1,090,516, March 17, 1914.)

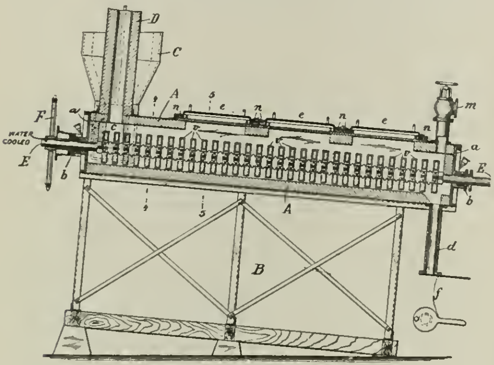

FIG. 2—APPARATUS FOR MAGNETIZING IRON-ZINC ORES

### Ore Cooler

In Fig. 3 is shown, partly in elevation and section, an ore cooler patented by Mr. Frederick Laist of Anaconda, Mont. The cooler consists of a drum which is set at an inclination to aid the passage of ore from feed to discharge end. Cooling is effected by a series of pipes placed along the inner surface of the drum, rceiving cooling water through pipe P. The drum is provided with water heads at both ends with which the pipes are connected. The water head at the feed end is not a part of the drum but is separated from it by space S. At this end the drum is closed by a plate through which the cooling pipes pass into the water head. The provision of this space permits expansion and contraction to which the drum is subjected. (1,090,549, March 17, 1914.)

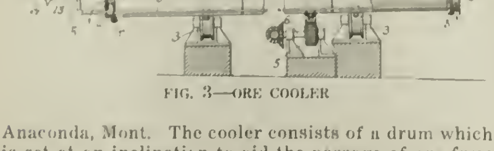

FIG. 3—ORE COOLER

### Aluminium

**Purifying Aluminium and its Alloys.**—The purification of molten aluminium from mechanically entrained impurities resulting from the melting of scrap metal may be accomplished by a flux of sodium chloride and sulphur, according to a patent recently granted to Mr. Grenville Mellen of East Orange, N. J. Molten sulphur and salt are thoroughly mixed and cast into rods which are then used to stir the molten aluminium which is to be purified. The sulphur vapors passing through the molten mass carry impurities to the surface where they form a flux with the salt. Additional fluxes such as sodium metaphosphate or zinc chloride can be added to the aluminium. The rod of salt and sulphur may contain 30 to 70 per cent salt. (1,092,935, April 14, 1914.)

An alloy of **aluminium**, zinc, copper, and silver has been patented by Mr. **William A. McAdams** of Bay Shore, N. Y. The metals are preferably combined in the proportion of 70 per cent aluminium, 26 per cent zinc, 3 per cent copper, and 1 per cent silver. The alloy will not tarnish and possesses great fluidity so that it will take the smallest impressions from a mold. (1,092,500, April 7, 1914.)

**Aluminium Solders.**—Mr. **Charles F. Grimm** of LeRoy, Minn., has patented a solder which can be applied to aluminium while the metal is cold. It consists of zinc 25 per cent, tin 50 per cent, lead 25 per cent. (1,093,403, April 14, 1914.)

A solder of **different formula** patented by Mr. **Auguste Cornande** and **Henri de Cruys** of Brussels, Belgium, consists of 52 per cent zinc, 17.5 per cent aluminium, 30 per cent tin and 0.5 per cent nickel. The nickel may be replaced by an equal amount of German silver. (1,092,340, April 7, 1914.)

### Alloys

**Acid-Resisting Alloy.**—An alloy which is said to resist not only the corrosive action of water and steam, but also that of sulphuric and nitric acids, is compounded as follows: Swedish iron 110 parts, nickel 90 parts, copper 1 part, aluminium 4 parts. Ordinary alloys of iron, nickel and copper have been objectionable because of the separation of the metals throughout the mass of the alloy. The inventor of the above formula, Mr. **Edward G. Gleason** of New York City, states that alloys within the proportions given above can be made without the use of any deoxidizing agent, and will be homogeneous and ductile. (1,093,557, April 14, 1914.)

**Making Titanium and Other Alloys.**—Various methods have been suggested for the reduction of refractory metals like titanium, and the production of their alloys with aluminium and copper. The objection to these methods, however, is they produce only alloys low in titanium, and when high titanium alloys are produced the metal is in the form of grains disseminated through the mass. According to the improved process of Mr. **Ernest Kraus** of Lynn, Mass., alloys high in titanium and other refractory metals can now be easily produced. According to one method, an intimate mixture of a compound of the refractory metal and a reducing metal, such as aluminium, is fed into an arc formed between a crucible and an electrode. When working thus with mixtures of titania and aluminium it is possible to get alloys containing as much as 94 per cent titanium. By a modified procedure the titania may first be fused in the arc, after which aluminium or copper or both may be added to the fusion. Reduction follows and a copper-aluminium-titanium alloy is produced. (1,089,773, March 10, 1914.)

### Metallurgical Furnaces

**Channel Furnace for Burning Ore Briquets.**—By the ordinary construction, channel furnaces are divided into upper and lower portions by the traveling hearth. The upper portion, in turn, is divided into a preheating chamber, a combustion chamber, and a cooling chamber. In order to utilize the heat of the burnt material, the combustion air is usually introduced at the rear of the furnace, in a direction opposite to the travel of the cars comprising the hearth, thereby preheating the air. The object of an invention of **Mr. Arthur Ramén of Helsingborg, Sweden**, is to provide an arrangement within the furnace whereby this preheated air from the cooling chamber will be introduced into the combustion chamber through a series of channels arranged in suitable relation with the gas inlets. In order to impart a suitable speed to this air and the gas with which it mixes, injector nozzles are arranged within the air channels, through which either preheated air or gas can be driven at a high speed.

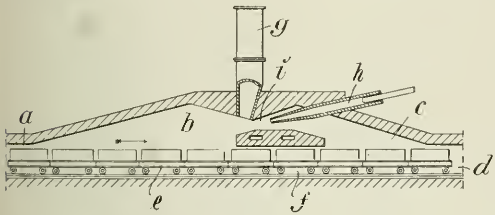

FIG. 4—CHANNEL FURNACE

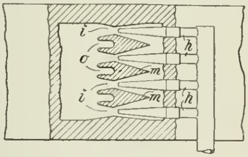

FIG. 5—ARRANGEMENT OF INJECTORS IN CHANNEL FURNACE

Fig. 4 shows a diagrammatic view of a channel furnace in which *a* is the preheating chamber, *b* the combustion chamber and *c* the cooling chamber. The gas inlet is shown at *g*. The tube *h* with the channel *i* forms an injector for introducing air (or gas) under pressure, thereby drawing in air from the cooling chamber *c*. Fig. 5 shows a plan of the arrangement, *m* representing partitions between the tubes *h* and the gas inlets *o*. The channels *i* may be used alternately for gas and air, thereby securing a "gallery" effect. A further advantage of the arrangement is a regulation of the quantities of gas and air over the entire width of the furnace, making it possible to use furnaces of three meters wide instead of 1.5 meters as before. (1,089,868, March 10, 1914.)

**The Fitz Gerald Laboratories, Inc.**, of Niagara Falls, N. Y., will carry on the business of Fitz Gerald and Bennie Laboratories, Mr. P. McN. Bennie having severed his connection with the latter.

### Mastic Lining for Acid Tanks

In connection with the operations of the Chile Exploration Company, in Chuquicamata, Chile, there has been developed a new method of lining concrete tanks which are subject to the action of sulphuric acid. Extended reference is made elsewhere in this issue to the nature of the metallurgical operations at Chuquicamata.

The company's copper ores in Chile are handled by the combined sulphuric acid and electrolytic method. After the ore is crushed it is put into large tanks or vats, and then leached with a 10 per cent sulphuric acid solution for forty-eight hours. The solution containing the copper is led through another process for extracting chlorine and then passes to the electrolytic tanks. There the copper is extracted and the remaining solution is then returned to the leaching vats ready for extracting the copper from a new batch of ore.

It can readily be seen that the large tanks required must be such as will withstand sulphuric acid, which, of course, concrete would not do unless provided with a protective lining. Experiments with tanks of various types were made, but in most instances proved failures. It was then suggested that an especially prepared acid-proof asphalt-mastic lining might be used to overcome the difficulties encountered. In coöperation with Mr. E. A. Cappelen Smith, consulting metallurgical engineer of the Chile Exploration Company, experimental tanks, among them one 15 ft. high, lined with Trinidad asphalt mastic, were installed at the research laboratory of the American Smelting & Refining Company, Maurer, N. J. With these tanks there was duplicated as nearly as possible the operation of extracting copper as it is carried out in Chuquicamata.

Under the direction of Mr. Smith various other materials were also experimented with at Maurer, but they all proved unsuitable, with the exception of the asphaltic mastic. It was on the strength of this material having shown no defects or deterioration after a year's test that the Chile Exploration Company has placed the contract for lining with asphaltic mastic some 150 concrete tanks or vats from 15 ft. to 16 ft. in depth and from 120 ft. to 150 ft. in exterior dimensions.

The lining of these tanks in Chile will require from 1250 tons to 2000 tons of asphaltic mastic, which is being prepared here and shipped to Chile. The first cargo of 500 tons was shipped in February, and as soon as it arrives, which will take about three months, as the ship has to go around the Horn, an experienced superintendent and nine mastic workers will be sent to Chile to do the lining of the tanks.

The experimental work at Maurer, the preparation of the asphalt mastic and its application to the concrete tanks was carried out by Mr. Henry Wiederhold, manager of the Vulcanite Paving Company.

---

### Removal of Arsenic from Sulphuric Acid

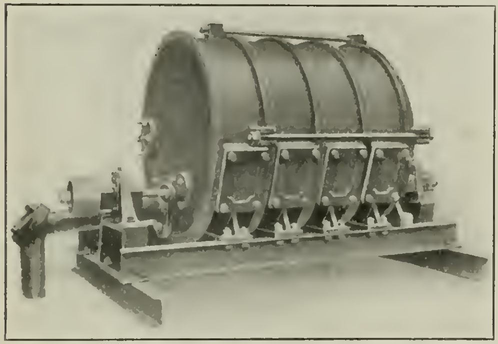
A new type of dearsenicator for the removal of arsenic from sulphuric acid is now on the market in the United States. It is different in principle from all the dearsenicators at present in use, the majority of which are the tower type. In all of these the sulphuric acid falls vertically over lead grids of various shapes which are so designed as to offer a large area to the action of the precipitant, which is hydrogen sulphide. The maintenance of these is expensive and repairs are frequent.

The Davis dearsenicator, which was developed by Davis Brothers, Manchester, England, and an outside view of which is given in the adjoining diagram, consists of an iron drum which is separated into several sections. This is lined completely with a special enamel which is quite resistant to sulphuric acid up to a temperature of 200 deg. C.

Inside each of these sections an enameled fan is placed so that about one-quarter of the blade dips beneath the level of the sulphuric acid passing through the drum container. These fans are attached to a common shaft and are revolved at between 40 and 60 r.p.m.

The object of the fan is twofold. It is designed to throw the sulphuric acid up as thin sheets and spray which enables the sulphuretted hydrogen to act very completely on the arsenic present in the acid. It also keeps the sulphuric acid, in each particular section, in constant agitation, preventing the settlement of the arsenic sulphide.

The vents in each section are so placed as to enable the sulphuric acid to run from one section to another until it reaches the outlet pipe. From there it is passed to filter tanks of special design. Schuler's filter tiles are used. The arsenic sulphide is completely filtered out here. The excess of sulphuretted hydrogen is either absorbed by caustic soda solution or milk of lime.



DEARSENICATOR

These dearsenicators are made in all sizes from 20 tons to 500 tons capacity weekly. They are remarkably efficient, giving a production containing from 1.5 parts arsenic per million to 1 part arsenic per million parts sulphuric acid. They will do this starting with an acid containing as high as 0.5 per cent arsenic and the average cost of treating per ton is 30 cents. There are a number of these at present in use in Great Britain, one of which has been in use for over two years without any deterioration or repairs. This type of dearsenicator never chokes up and never requires cleaning.

It also occupies less space than any other type at present in use.

Dearsenicators for sulphuric acid are of a special interest on account of the even more stringent requirements of the recent pure food and drug act.

Acid made from pyrites and treated with hydrogen sulphide in this manner is more pure than acid ordinarily made of sulphur as all the lead, copper, antimony and bismuth are also, of course, completely removed. For this reason the new dearsenicator should be particularly welcome to all who have experienced troubles from the pure food and drug act.

The dearsenicator having a capacity of 200 tons O. V. per week occupies a floor space of about 6 ft. by 3 ft. 6 in. and weighs approximately 3600 lb. The Davis "Trepex dearsenicator" is being introduced in this country by Industrial Research, Inc., 50 East Forty-first Street, New York City.

## Improvement in Forging Practice

Notwithstanding the fact that the need for increased efficiency has long been apparent in forge-shop practice, practically all of the progress has been on machine design, and the heating side has been either too lightly considered or entirely overlooked, although in many cases the cost of heating is greater than that of operating the machines. The result has been that the output of the modern machines has been restricted by the inability of the furnace and the man to keep up with them, and worth while savings in cost of manufacture lost. This is particularly true in connection with the heating of small and medium-size work, such as bolt and nut stock, wrench and hammer parts, springs, shears, snips, cutlery, and a great variety of general drop forging and light hammer work.

Forge furnace design and principle of operation have been quite generally befogged by discussions of fuel prices, burner efficiencies, and other details merely incidental to the operation; and too little attention has been paid to the basic principles of proper combustion, chamber provision, protection for the stock, even heating, etc., as well as the more practical question dealing with the protection of the operator.

Efforts have been made to reduce fuel consumption, but in practically all cases the progress in this direction has been at the expense of the quality and quantity of the stock handled, due to the fact that the efforts made to remedy the difficulty have been along the lines of dealing with the effect instead of the cause.

To relieve these conditions the W. S. Rockwell Company, furnace engineers, 50 Church Street, New York, have patented and introduced a new type of forge furnace which not only makes it possible for the operator to work to better advantage and keep up with his machines but offers other inducements in the way of decreased operating costs.

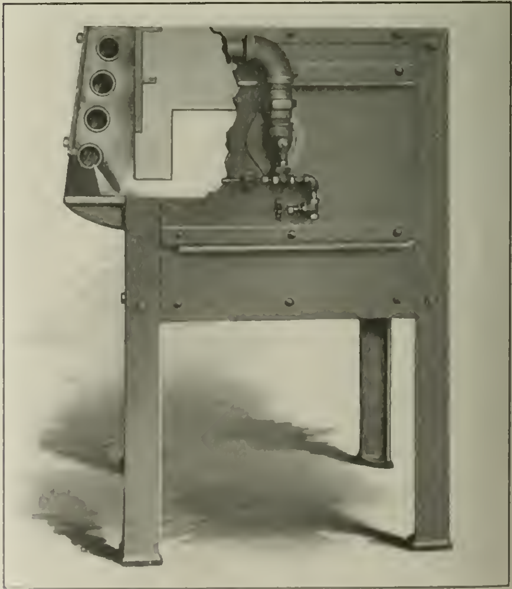


FIG. 1—FORGE FURNACE

The furnace has been successfully tried out under actual working conditions in the manufacture of a variety of products, and its worth has been demonstrated in competitive operating tests which have led to its adoption in a number of large installations.

The design of the furnace, as shown in the illustrations, involves, among other features, a special economizer shield over the working opening, which recovers a large percentage of the heat ordinarily wasted, and also a novel arrangement of blast which acts as a barrier between the operator and the heat and enables him to work closer to the furnace and handle his material faster and with less effort and discomfort.

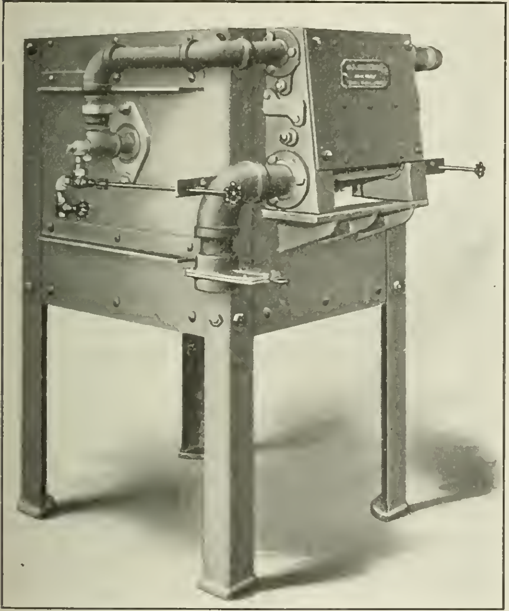

FIG. 2—FORGE FURNACE

In the operation of the furnace the spent gases discharged from the working opening are deflected by the blast away from the operation and against the tubes and headers of the economizer, through which the air for combustion is circulated, with the result that the air, taking up heat in its passage, is delivered hot into the furnace with the fuel.

The utilization of the waste heat not only means economy in fuel, but in the volume of air introduced into the furnace, which not only tends to decrease the power required to deliver the air, but the amount of oxidation as well.

The provision for combustion is such that the heat is applied uniformly on all sides, and the ill effects of varying temperature or composition of the usual "flame" are eliminated. There is a thorough mixture of the gases, which, with the help of the heated air, makes it possible to maintain clean, soft, soaking heats, which in practice have been found to materially reduce the amount of scale on the stock and in some instances to the extent of doubling the life of the dies.

In front of the working opening is a blast forming a curtain of air under pressure, through which the operator works and the full mechanical effect of the pressure is available all the time, or whether the stock be partly without or entirely within the furnace chamber. This blast not only acts to deflect the waste gases into the economizer, but to protect the operator as well, and it has been found in tests running over a period of several months that the more comfortable working conditions enable him to handle his material to much better advantage and in some instances from 60 per cent to 75 per cent more than had previously been heated in the same hearth area.

The advantages of the construction include reduction in consumption of fuel and air, protection for the operator, greater output for the same heating area, reduction in amount of scale, increased die life, as well as cleaner shops and more healthful working conditions for the men, with less heat, smoke, noise and dirt.

## Silico-Manganese

The following notes on silico-manganese, made by the Vargöns Company at Trollhättan, Sweden, should be of interest, as this alloy has found considerable use in European steel works as a substitute for ferrosilicon and ferromanganese.

The silico-manganese has the following analysis:

| | |
|---|---|
| Silicon and manganese together...... | 90.096 per cent |
| Phosphorus .................. | 0.030 to 0.070 per cent |
| Sulphur ..................... | 0.010 to 0.015 per cent |
| Carbon at 17 per cent silicon abt........... | 2 per cent |
| Carbon at 25 per cent silicon abt.... | 0.3 to 0.5 per cent |
| Carbon at 30 per cent silicon abt.... | 0.1 to 0.2 per cent |

The proportions of silicon and manganese can be varied so that any alloy containing between 17 to 50 per cent silicon and the manganese between 73 or 79—40 or 46 per cent can be had.

The addition of silico-manganese to the molten steel is done in the same way as for ferromanganese and ferrosilicon.

The advantages claimed for the use of silico-manganese are as follows:

Ferrosilicon and ferromanganese (especially ferrosilicon) add, as well known, to the molten steel a considerable amount of cold iron, which is cooling down the steel at a critical moment; the silico-manganese, on the contrary, is composed almost entirely of manganese and silicon, and therefore the chilling effect is very much reduced.

The manganese is better protected for oxidation on account of the perfect mixture of silicon and manganese in this alloy; therefore the amount of manganese to be added is less than if using ferromanganese. In fact, experience shows a saving of about 10 per cent.

It also follows that it is easier to attain the exact amount of manganese in the steel.

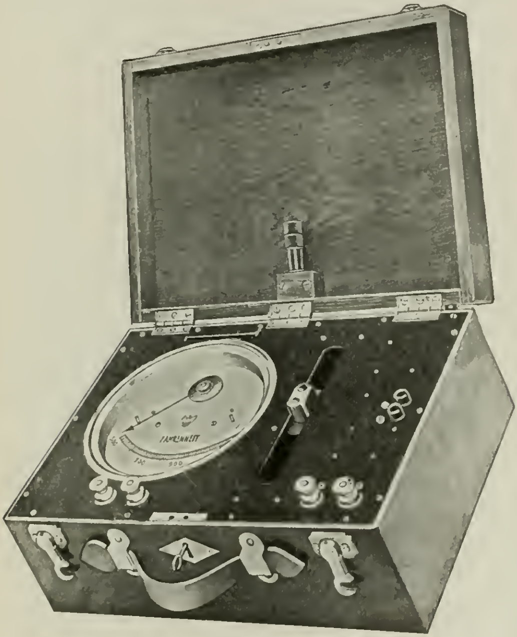
The percentage of carbon in the silico-manganese is low in comparison with ferromanganese, which of course is of great benefit, taking into consideration the recarburizing through the alloy. This is especially important in producing soft steel, and experience has shown that time is saved in making a heat, which means lower costs.

The silico-manganese is made from very pure Swedish manganese ore, very low, as shown by analysis, in phosphorus and sulphur. This has proved to be of great value in producing high-quality steel.

The American Bridge Co., Chicago office, confirms the report that it has the contract for 6000 tons of steel from the International Smelter & Refining Co. to be used in the erection of a new smelter at Miami, Ariz., to cost about $2,000,000. D. A. Welch, Butte, Mont., of the Anaconda Copper Company, is purchasing agent.

## Combination Portable Testing Set Using Resistance Thermometers and Pyrometers

For those requiring a temperature measuring instrument for low, intermediate and high temperatures, a recent development by the Hanovia Chemical & Manufacturing Company, of which Mr. Charles Engelhard, 30 Church Street, New York City, is the president, will be of special value, combining, as it does, instruments for widely varying temperatures in a compact, convenient form for portable use. The instruments employed are Heraeus quartz glass resistance thermometers and the well-known Heraeus Le Chatelier pyrometers.



COMBINATION TESTING SET

The resistance thermometers consist of a resistance spiral of chemically pure platinum, which is imbedded in quartz glass, thus insuring no contamination of the resistance spiral by injurious gases and no change in resistance by evaporation. These thermometers are mounted in any form suited to best meet the requirements of the purpose for which they are to be used. Their temperature range is from —330 deg. F. to + 1300 deg. F. and an accuracy of $\frac{1}{2}$ of 1 per cent of their scale range is guaranteed.

The Heraeus Le Chatelier pyrometers are too well known to require detailed description here. For use with the combination portable sets, they are mounted in a convenient portable form, suitable for the measurement of temperatures up to 3000 deg. F.

Only one indicating instrument is used which is graduated with two or more scales, depending upon requirements. The thermometer scales may be between any desired limits within the range of the thermometers themselves, and the pyrometer scale is graduated from 32 deg. F. to 3000 deg. F. For example, the indicating instrument could have two thermometer scales, one graduated from 30 deg. F. to 300 deg. F. and the second from 500 deg. F. to 1000 deg. F. and the pyrometer scale from 32 deg. F. to 3000 deg. F.

The sets can be supplied for practically any number of thermometers and pyrometers, and the change from one scale to another and from one thermometer or pyrometer to another is made by the pressing of a button.

The indicating instrument, and all switch and regulating arrangements, are neatly mounted in an oak carrying case, which can be carried inside of an ordinary suit case. The thermometers and pyrometers are also provided with a suitable carrying case.

The special field for these instruments will, of course, be for portable testing work—as for example, in power plant testing, for consulting engineers, demonstrators, etc.

As a practical illustration—in boiler testing the pyrometers could be used in the firebox, flues and stack, and the resistance thermometers in feed water, economizers, condensors and superheaters. One man can take all these temperatures practically simultaneously, and at a point anywhere convenient to himself, as the distance between the thermometers, pyrometers and indicating instrument does not in any way affect the accuracy of the indicated temperatures.

These instruments will fill a long-felt want for a suitable means of accurate testing, where widely varying temperatures must be measured and where requirements demand a compact and easily transportable instrument.

---

## Uses of Asbestos and Its Products in Chemical and Metallurgical Industries

Asbestos holds an unique position among minerals on account of its peculiar physical properties. Since its original discovery it has found a wide variety of industrial applications and has been transformed from a mineral curiosity into an industrial necessity. When treated mechanically it yields soft, white, delicate and exceedingly strong fibers, which can be spun, woven and otherwise manufactured into many useful articles. In addition to its fireproof qualities it is acid-proof and practically indestructible. It also forms a valuable insulator for electrical purposes. Just how extensively asbestos products are used may be gathered from the fact that the H. W. Johns-Manville Co., New York, manufacturers of asbestos products, occupies its own skyscraper business building in New York City (quite close to the Chemists' Club), and maintains forty branch offices in different parts of the United States.

As a heat insulator asbestos finds application in a way that directly affects the cost-sheet. The loss from radiation and condensation due to uncovered or improperly covered pipes, boilers, or furnaces directly affects the coal pile. High-class insulation is absolutely imperative owing to the present high cost of fuel and the growing demand among manufacturers to reduce the unit cost of production to a minimum. Every dollar wasted in fuel consumption detracts from the earning capacity and the profits of the plant. Asbestos insulating materials are the outcome of careful, practical experiments in this field, and have demonstrated through many years of hard service their peculiar adaptability to the purposes for which they are recommended, and the maximum earning power in coal saving. The best insulation is none too good to meet the increasing severity of modern requirements.

Asbestos pipe coverings are made in a variety of forms, such as a mixture of asbestos fiber and magnesia; a light cellular construction of asbestos paper, and a combination of molded asbestos with a covering of wool felt. Other forms of insulation are made for brine, ammonia, ice-water and cold-water pipes.

It is quite as important to cover boilers, domes, cylinders and large surfaces as it is to insulate pipes. For this purpose asbestos sheets and blocks are used, under conditions where the expansion and contraction of large surfaces would injure cement coatings. Insulating cements of asbestos and magnesia, mixed with water to the consistency of mortar, are applied as coatings over sheets or blocks.

Among the most annoying items of expense in boiler maintenance are the up-keep of fire-brick walls and arches and the cost of delay in cooling down a boiler for repairs. This is largely due to the inefficiency of fire-clay—which heretofore has been the only available bond for setting up fire-brick.

Fire-clay readily fuses and runs, opening up the joints between bricks. In addition to this refractory bricks are porous. Hot gases of combustion enter into the pores of the bricks and into the joints when the fire-clay has fused out, weakening the bricks and eventually causing the whole wall to break down. Cements of asbestos and other refractory materials have been found useful, preventing these conditions.

A plastic asbestos retort cement has found application in gas and chemical works for repairing broken clay and iron retorts and pipes, and cementing fittings, connecting pipes and flange-joints, also for cementing joints in stone, wood and metal. It can be easily applied with a trowel. It hardens rapidly, vitrifies without shrinking when subjected to intense heat and is fire and acid-proof. It is not injured by acids, petroleum oils, etc., and effectually prevents the escape of vapors.

Acid-proof cements are now made which meet other needs in the chemical industry. To the users of acids, either in concentrated or diluted form, the problem is ever present of how to convey them to different points at least possible cost, without the possibility of leakage, resulting in damage to stock and machinery as well as building, also loss of money by waste of acids.

Acids, even in diluted form, will gradually disintegrate and destroy iron and wood, and will in time make a building unsafe.

The storage of acids in bulk and the use of same in tanks is a still further source of trouble because of danger of leakage and subsequent damage. These problems can be solved by the use of a particular form of acid-proof cement.

Of interest to the foundry and machine shop are certain metallic compounds made by the Johns-Manville Co. These are used for smoothing over and filling up blow-holes and sand-holes in iron and steel castings, making pipe joints and stopping leaks in steam, water, gas, oil, ammonia and brine pipe-lines without removing them from position.

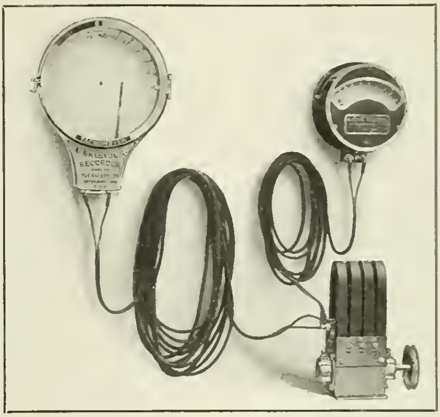
Asbestos roofing material is now widely used in the protection of buildings used for chemical, metallurgical and other industrial purposes. In addition to the qualities possessed by other roofing materials, asbestos affords fire protection and acts as a heat insulator. A roofing material composed of asbestos felt impregnated with refined asphalt gives service that makes its use inexpensive when cost of maintenance is taken into consideration.

A great deal of detailed information regarding these and other asbestos products is contained in a long series of catalogs and bulletins issued by the H. W. Johns-Manville Co., Forty-first Street and Madison Avenue, New York City. Any of these publications will be sent on request to applicants who are especially interested in the subject.

## New Electric Tachometer

The field of usefulness for recording tachometers includes use in connection with all engines, machinery or revolving shafts wherever information is desired about the rate of speed at which shafting or any other devices are revolving. Some of the most important applications are in connection with engines, turbines, generators, paper machines, blast furnace blowing engines, motors and pumps. Recording tachometers are usually required for continuous service under ordinary shop or mill conditions and for this reason must be made rugged and durable to be thoroughly successful.

A new Bristol electric tachometer of the alternating-current type which is particularly well suited to rough operating conditions in mills, power plants or shops is being put on the market by The Bristol Company, Waterbury, Conn. Although this is an electric tachometer, no sliding contacts or brushes are used in it and no delicate millivoltmeter movements are required.



ELECTRIC TACHOMETER

Two of the most important features of this electric tachometer which make it particularly strong and durable are the induction magneto and the voltmeter movement. The magneto as shown in the accompanying illustration is of the induction type without any sliding contacts or brushes. The indicating and recording instruments are voltmeters. The indicating instrument is equipped with a Weston pivot jewel-bearing voltmeter movement. The recording instrument is equipped with an improved Bristol voltmeter movement so designed that there is plenty of power available for actuating the recording arm even though the recording pen is in continuous contact with the surface of the chart. In this recorder the movement is mounted on frictionless knife-edge bearings. This movement is equipped with a new patented supporting device for the moving elements designed to eliminate temperature error. This recorder can be furnished for use with either 12-in., 8-in. or 6-in. charts.

The accompanying illustration shows a combination indicating and recording unit which provides an indicating instrument for the operator at his post of duty and a recording instrument for the superintendent or foreman in his office. By the use of suitable lengths of leads, either instrument can be placed at almost any point desired, and more than two instruments can be connected to meet special conditions.

## A Novel Branch of Research

"Research work on research apparatus" sounds rather extreme, yet is actually done in Pittsburgh in a very practical way. The demand for a research department came to the Scientific Materials Company in connection with their regular laboratory supply business.

Special apparatus for research is not, however, the only line of work followed by this department, as it also carries on the work which deals with the designing and testing of all new apparatus or improvements in existing types.

This new department really marks an epoch in the development of this company and illustrates how the field of laboratory apparatus has grown. Five years ago the business of supplying laboratories was in itself considered a specialty, yet today it has become necessary to specialize in this same field. In the beginning the demand for different apparatus was comparatively small in each instance, and the natural tendency was to adopt the nearest thing available, at least in part. But the rapid advance in science has caused a demand for a corresponding advancement in scientific apparatus, and the work of meeting this demand now requires a separate organization of its own.

This specialization by means of a separate department for designing and improving apparatus bids fair to add its share to the great progress now being made in chemistry, metallurgy and biology. This is especially so when we consider that many scientific discoveries follow in the path of improvements in the apparatus with which the scientist must work.

In organizing this special work the idea of the late Robert Kennedy Duncan of isolating the men with their problems has been carried out, and this department is relieved of all responsibility of routine, manufacturing, etc. The responsibility of the research department ends after a new piece of apparatus has been designed, tested out and turned over to the sales end of the organization. The many laboratories about Pittsburgh, including the United States Bureau of Mines, the United States Bureau of Standards, the Mellon Institute of Industrial Research and others, were constantly requiring special apparatus in connection with their research work. The men employed in the laboratories, however, had their own problems to solve and preferred to be relieved of the work in connection with the designing and testing of the necessary special apparatus.

The Scientific Materials Company was called upon for this work, and by adding it to the original work which they had been doing in designing and improving apparatus for the regular market, they found that a separate department was necesary to carry on the work successfully.

The department is in charge of a graduate electrical engineer who gives it his whole time and acts as director. He is assisted by a graduate chemical engineer, a sanitary engineer, a mechanical engineer, a pyrometric engineer, a mining engineer, an expert glass blower, and two precision mechanics. At the present time five of these men give their entire time to the research work, and as all the other men are in the regular employ of the company they work from time to time in connection with the others just according to the problems on hand, and also act in a consulting capacity.

When a particularly difficult problem arises, a conference of the staff is called and the problem is presented by the director, and after a general discussion the different ideas and suggestions are obtained. This is very valuable as the staff, on account of their different lines of training, view the problems from as many different angles.

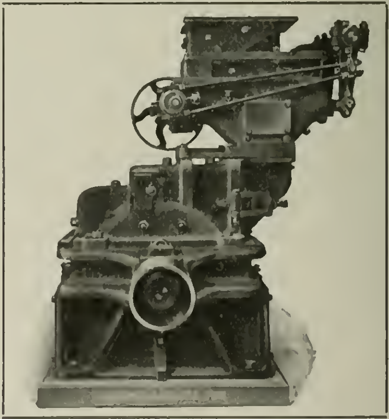
The reference library used in connection with this work is also unique in that it embodies the catalogue file of the import department of the same company, which contains the trade literature of practically every scientific apparatus manufacturer throughout Europe.

This work has been going on for some time and the first bulletin, "Errors in Bacteriological Incubation," has been issued. This bulletin gives in condensed form an outline of the difficulties encountered, especially in incubators, and tells in detail how they are now overcome in a perfected form of apparatus.

## Hammer-Bar Pulverizer

The Sturtevant Mill Company of Boston, Mass., have placed on the market a machine which is claimed to be an improvement on other impact pulverizers both mechanically and in principle of operation. The Sturtevant hammer-bar pulverizer crushes soft and moderately hard materials (up to and including all limestones in hardness). It represents the greatest efficiency in a mill of this class.

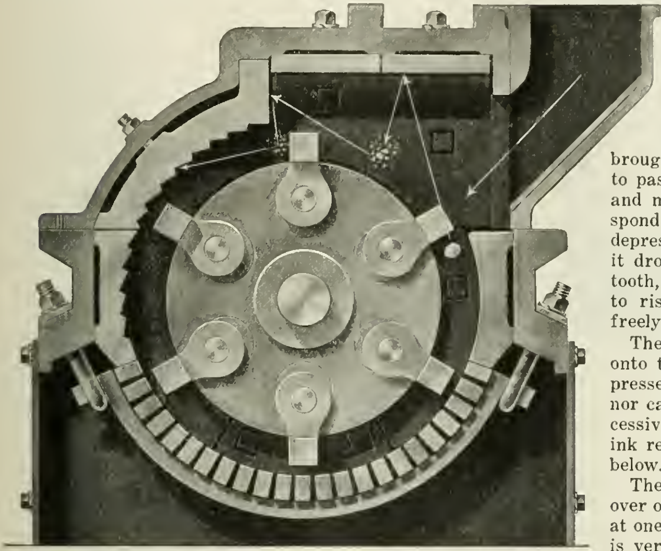
The material fed may be as large as 4″ to 5″ in size, with soft rock, varying to 1½″ to 3″ for harder substances.



HAMMER-BAR PULVERIZER

The rock is fed from an automatic feeder which drops it on the heavy hammer-bars of manganese steel which move *upward* to meet it at high velocity (just as the bat meets the flying base-ball). The impact is tremendous and the rock is smashed up against an armor breaking plate, from which it rebounds against another hammer bar swung up against it with the same smashing effect. Thus are dealt, against the rebounding rocks, a succession of terrific blows, and plate collisions (that recur 7200 times a minute), resulting in an immense output of powdered stone.

It should be noted that the smashing action already described represents the *upward* stroke of a bar hammer against rock rushing to meet it. The result attained represents the highest possible efficiency. But when the hammer bars begin their downward path, efficiency is so diminished (the bat chasing the ball strikes a feeble blow) that another plan must be adopted—and the descending hammer bar is now brought close to a corrugated breaker plate where the greatly reduced broken stone is further pulverized between the high-speed hammer bar and the corrugated plate in close relation thereto. The hammers now pass close to the bar grate, made of the hardest steel, 1¾" deep. The ground rock dashed through the openings of the grate is sufficiently pulverized, and is now violently ejected from the case. This relieves the hammers which otherwise would drag through material already sufficiently reduced. Thus there is no finished rock left to repeat the circuit and waste power.



INTERIOR VIEW OF HAMMER-BAR PULVERIZER

It is clearly seen that as soon as the hammers begin to rush upward again against the incoming rock, they resume their work of rock destruction.

This mill is built extra heavy, and runs with practically no vibration, as it is perfectly balanced, and the hammer bars, held strongly out by centrifugal force, revolve with the sustained regularity of a heavy balance wheel. The bearings are of ample proportion, self-oiling, and dust proof. The hammer bars are of manganese steel, and the screens of the hardest and strongest material obtainable. "Open-door" construction affords immediate access to the interior of the case for inspection, and replacement of hammers, or grates, or screens.

## New Recording Pyrometer

A new recording pyrometer, recently perfected by the Thwing Instrument Company of Philadelphia solves the problem of "how to carry water in a bottomless pail," the chief feature of the recorder, from the standpoint of originality, being the new capillary ink-pad.

Fig. 1 illustrates the principle upon which this new ink-pad operates. A horizontal plane of brass is mounted above the drum which carries the chart. In this plane of brass, or ink-pad, is a circular well (C), which is filled with ink, and a V-shaped groove (D), corresponding to the arc through which the needle (E) will travel, as actuated by the thermoelectric force of the thermocouple. This V-shaped groove is open at the bottom, so that the needle (E) may be depressed through the groove upon the chart below.

As the inkwell (C) is filled the ink spreads by capillarity to the extreme end of the groove, so that a film of ink separates the needle, when elevated, and the chart. The depressor arm (G) is attached to a depressor lever mounted on the face of the clock, in the lower section of the recorder case, the clock also being employed to drive the drum carrying the chart. Underneath the depressor lever, on the clock face is a contact wheel having regularly spaced teeth with a gradual rise and abrupt drop.

As the depressor lever travels on the rise of the tooth the depressor arm (G) is raised, tilting the actuating lever (A) so that the depressor bar (B) is brought down upon the needle (E), causing it to pass through the film of ink in groove (D) and make a dot of ink upon the chart, corresponding to the temperature and time. As the depressor bar reaches the summit of the tooth it drops abruptly into the bottom of the next tooth, drawing (A) downward and causing (B) to rise, permitting the needle (E) to swing freely above the groove (D).

The ink will not follow the needle (D) down onto the chart, even though the needle be depressed long enough to make a continuous line, nor can it be jolted through the groove by excessive vibration, but remains a clear film of ink ready for countless records upon the chart below.

The advantage which such a recorder has over one which must return to an inkpad, placed at one side of the chart, for a new supply of ink is very apparent. The frequency of record is much higher with this capillary type of inkpad, as the needle is always in circuit with the thermocouple and is always at the correct position for temperature record, hence it is merely a matter of the frequency with which it is desirable to depress the needle upon the chart.

This type of inkpad has been used for about a year by such gas companies as the Consolidated Gas Co. of N. Y., United Gas Improvement Co. of Phila., for recording temperatures of water gas machines. On the carburetors of such machines it is necessary to secure frequent records of temperature, as the temperature rises and falls very rapidly as the oil is sprayed into the carburetor, the cooling of the gas

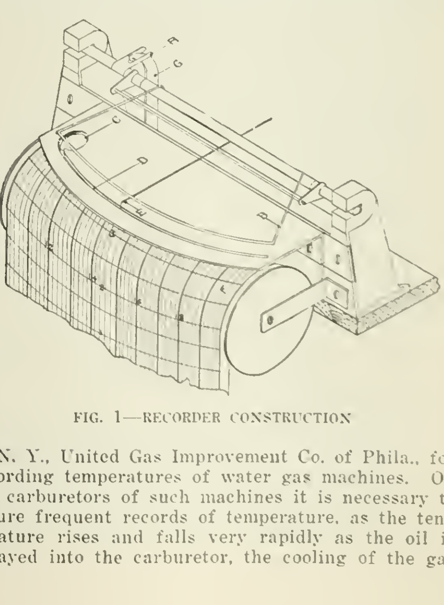


FIG. 1—RECORDER CONSTRUCTION

as the oil is turned on and its return to the proper temperature covering several hundred degrees in a space of a few minutes. With three records per minute, as made by the capillary inkpad, it was found that practically a continuous line was obtained, each operation being rendered distinct by its minimum and maximum temperature.

Another field in which this type of inkpad is invaluable is in constructing "cooling curve" recorders, for with a high chart speed and ten, fifteen, twenty or even thirty depressions per minute, it is possible to provide a very open, graphic curve showing the behavior of the specimen under treatment. It is also especially valuable in the automatic temperature controlling and recording apparatus, which the Thwing Instrument has recently developed.

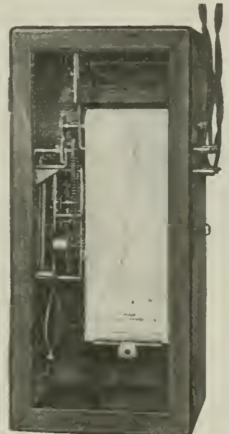

FIG. 2—RECORDING PYROMETER

A complete recorder ready for use is shown in Fig. 2.

## Notes

**The Chicago Section** of the American Chemical Society is compiling a census of the chemical laboratories, chemists, and chemically trained men within a radius of 40 miles of Chicago. Companies and individuals who maintain such laboratories or employ chemists are requested to communicate such facts to the Secretary of the Chicago Section, Mr. D. K. French, 2005 McCormick Bldg., Chicago, Ill.

**Electric Zinc Smelting.**—The American rights for electrothermic treatment of complex zinc ore are now controlled by Johnson Electric Smelting, Inc., Room 1802, 18 East Forty-first street, New York City. Byron E. Eldred, is president, W. McA. Johnson is first vice-president, Joseph Struthers second vice-president, and Phillip Mallery secretary and treasurer. The designs for a 10-ton unit are about finished, and the furnace is expected to be working in the fall.

**The Electrolytic Gas Company** has been organized by Mr. E. F. Platt, formerly connected with the Platt Iron Works of Dayton, O., and Mr. C. A. Kurz, Jr., of the Kurz Laboratories. This company has secured the western selling agency of the International Oxygen Company of New York, and it is the intention of the company to proceed with the installation of a number of electrolytic plants of the I. O. C. System for the production of oxygen and hydrogen in different parts of the country.

**The American Platinum Works**, at Newark, N. J., has issued a new illustrated catalog on their manufactures. The booklet contains also some timely hints on the care of platinum ware, as well as valuable tables of weights and measures.

**In drying apparatus** of the type made by the Ruggles-Coles Engineering Company, New York, the exhaust gases are at a temperature of about 100° F., so that an exhaust fan may be used. By increasing the speed of the fan an increased capacity of the dryer may be obtained in almost direct proportion. Additional interesting information about dryers is contained in a catalog recently issued by the company.

**The Patterson Foundry and Machine Co.** states that, contrary to the general belief of the existence of a general business depression, they have been so rushed with orders as to find it necessary to build an addition to their Upper Works at East Liverpool, Ohio. They are also now considering the increase of the capacity of their Lower Works and an increase in their structural and steel plate department. All of the Patterson products are made entirely in the Patterson shops, including all parts of all machines. To take care of their rapidly growing trade in the East they will open shortly a fully equipped New York office. Mr. Edward W. Lawler, formerly with the Abbe Engineering Company for a number of years, will be in charge of this office and represent the Patterson Foundry & Machine Company in New York and adacent territory.

**Two new white-metal alloys** of silver and aluminum, known as "argental" and "macadamum," are said to possess properties that make them superior to other metals for certain uses. They take a high polish, do not tarnish or corrode, and can be cast or rolled. The alloys are marketed by the North American Selling Company, 120 Liberty street, New York City.

**Baker & Company, Inc.**, of Newark, N. J., have recently added a new factory and office building to their plant. The structure will be devoted to the manufacture of platinum wire, sheet and tubing, as well as crucibles and dishes for chemical purposes. Extensive additions are also planned for the refining and research departments which will occupy the building formerly devoted to the manufacturing department.

**The Check to Dampness** is the title of an attractive edition of their "Red Book" just issued by Toch Brothers, 320 Fifth Avenue, New York City. It contains valuable data for the architect, engineer and builder who wishes to keep posted on the latest developments in materials for the preservation and decoration of every type of building construction. Toch Brothers for years have been inventors and manufacturers of technical and scientific paints, enamels, varnishes, etc., and this book is replete with data pertaining to materials which are proof against all destructive agencies—acids, alkalies, electrolysis, locomotive fumes, etc., and, in addition, contains authoritative data on the integral waterproofing of dry docks, tunnels, swimming pools, reservoirs; also the treatment of cement floors in warehouses, automobile plants, loft buildings, power houses, public and private buildings.

**The Badger Chemical Diary** for 1914, issued by the E. B. Badger & Sons Company of Boston, Mass., contains in a very convenient form besides the usual diary, maps of different sections of the United States and illustrated notes on various products of this firm, such as stills, evaporators, vacuum fans, dryers, autoclaves, lead and silver-lined apparatus, etc. Some useful tables are added.

**Coal briquets** to the amount of 181,859 short tons, valued at the plants at $1,007,327, were manufactured in 1913, according to Edward W. Parker, of the United States Geological Survey. The figures for 1913 show a decrease of 17 per cent in the tonnage of briquets manufactured, but an increase of over $5\frac{1}{2}$ per cent in value over the figures for 1912. Seventeen briquetting plants were in operation during the year, eight in the Eastern States, five in the Central States, and four on the Pacific coast. Seven of these plants used anthracite culm or "fines," five used bituminous or semi-bituminous coal, two used carbon residue from oil-gas works, and the others used mixed coals. Coal-tar pitch is the principal binder employed, eight plants using it. Patented binders were used at five plants.

## Paul Heroult

Out of the international group of the few great men who are the creators of modern industrial electrochemistry, Paul Héroult has gone into eternity. A sketch of his life is given elsewhere in this issue, but no such sketch can indicate the elemental greatness of the man whose loss we mourn. Héroult could have become a great mechanical engineer, but destiny made him a pioneer of electrochemistry. People wonder why Héroult and Hall should have found the same process of reducing aluminium simultaneously and independently in France and America. They might just as well wonder why it rains simultaneously in two places, if the air is oversaturated with water vapor in both. Humanity was ripe for the birth of industrial electrochemistry and the intellectual atmosphere was oversaturated with the ideas of its possibilities. Destiny's problem was to find the men who would be the nuclei of condensation. Héroult was one of them and in the history of mankind he will live forever as the pioneer of the electrometallurgy of aluminium and steel.

But in destiny's hands it is the man as man that counts. And those who knew Héroult best, loved him most as mere man. For ourselves we can say no more than that this journal has lost in him one of its oldest and truest friends. For all of his many friends all over the world we know we can say that though Héroult has gone, the memory of his genial personality will remain an everlasting inspiration.

## Iron and Steel Output in 1913

With the appearance in the past fortnight of additional statistics of steel production in 1913 some interesting comparisons can be made. The 1913 statistics as far as reported are embodied in the following table, the figures referring to gross tons except in the case of nails:

| | 1912. | 1913. | Change. Per Cent. |
|---|---|---|---|
| Pig iron ........... | 29,726,937 | 30,966,152 | + 4.16 |
| Rails ............... | 3,327,915 | 3,502,780 | + 5.26 |
| Structural shapes .. | 2,846,487 | 3,004,889 | + 5.55 |
| Rods ............... | 2,653,553 | 2,464,807 | — 7.12 |
| Wire nails (kegs)... | 14,659,700 | 13,559,727 | — 7.50 |
| Cut nails (kegs).... | 978,415 | 842,038 | —13.90 |

The outstanding feature in the comparison is the decline in rod production. While rods are used for the production of chain, the great bulk of the output is consumed in the manufacture of wire so that the decline in rod tonnage may be regarded as a decline in the production of wire. The production of wire nails, it may be noted, decreased in substantially the same ratio as the production of rods. The greater decrease in cut nail output represents no new trend, for the cut nail output has decreased nearly every year since the maximum was reached in 1886, or since the wire nail began to come into vogue.

Fifteen years ago the statisticians were making predictions that eventually the production of rods would exceed the production of rails. It was an interesting thing to say, and the bare figures appeared to furnish adequate support. The production of rods had increased from 279,769 tons in 1888, the first year for which statistics were gathered, to 1,071,683 tons in 1898, an increase of 282 per cent. Rails had made the poor showing of being unable to surpass the tonnage made as far back as 1887. Those statisticians, however, overlooked certain things. Fully one-third of the 1898 production of rods went into nails, and this represented quite largely a displacement of the cut nail by the wire nail, a displacement then almost completed. They overlooked also that wire products were purchased and consumed by the people for their ordinary daily requirements, hence the five-year industrial depression from which the country was emerging had not very seriously curtailed wire consumption. On the other hand, the railroads were very poor. A large percentage were just emerging from receiverships. In 1899, a year of great activity in iron and steel, the rod production actually decreased, whereas rail production made a new record, at last passing the tonnage of 1887. From 1899 to 1906 rail production increased 78 per cent while rod production increased 84 per cent., rods, therefore, making hardly any gain over rails. Since 1906 there has been some good reason, however, for repeating the old prediction, since from 1906 to 1913 rail production decreased 12 per cent., whereas rod production increased 32 per cent., and in 1913 rods amounted to 70 per cent., as large a tonnage as rails.

Reverting to the comparison between 1912 and 1913, it is remarkable that rails and structural shapes made gains slightly greater than were made in pig iron, and rods, a light product, showed a loss, for the steel trade philosophy of recent years has been that the gains in tonnage were likely to be made by the light products, particularly in years in which financial conditions were not especially favorable to the launching of big enterprises. These big enterprises involve the consumption of structural shapes very largely, and it is commonly held that in no year since 1906 have conditions been nearly as favorable as in that year for the financing of such things. Nevertheless, we find that the production of structural shapes increased 41.9 per cent., while the production of pig iron increased only 24.3 per cent. Given such an expansion in new construction and the launching of big enterprises as is to be expected some day, the tonnage of structural shapes promises to show further large gains. In 1913 they fell only 14 per cent. under rails, when 15 or 20 years ago their tonnage was almost insignificant.

## Sweeping Decision in Flotation Litigation

The United States Circuit Court of Appeals for the ninth circuit, sitting at San Francisco, handed down on May 4 a decision in the case between James M. Hyde and Minerals Separation, Ltd. The latter had brought suit against the former as infringing Minerals Separation flotation patents, and had secured a favorable decision in the lower court. The Court of Appeals reversed this decision and upset Minerals Separation patents on concentration by flotation.

The decision is of wide interest and has been awaited impatiently by many metallurgists who were concerned in one way or another with the future of flotation in this country, and who viewed with apprehension the prospect of a monopoly in that new and promising branch of metallurgy.

The language of the court is forcible, clear-cut and unequivocal and the point of view on which the decision is based is interesting. The basis of novelty and invention claimed by Minerals Separation lay in the formation of a froth containing concentrates produced by agitation of pulverized ore in water, by the action of oil in quantity less than 1 per cent of the ore treated. The froth and the minute quantity of oil were the main points. The court reviewed the patents in the art beginning with those of Haynes (British) in 1860, and Everson's (U. S.) in 1886, and found each of the steps in Minerals Separation's process "fully described in more than one of the patents of the prior art, with the single exception of the reduced quantity of oil." The mere formation of a froth by agitation was held to be anticipated in the prior art.

The attitude of the court regarding the small quantity of oil used in the Minerals Separation process was that reduction in the amount of oil required for flotation was only a logical development in metallurgical economy and efficiency such as any progressive concern would bring forward in the course of its investigations. The mere use of a smaller quantity of oil than in other processes is, therefore, held not to be sufficient to constitute invention, for this difference is one of degree and not of kind. To hold such a claim valid would be "to take from others the right to use oil economically." Quoting from another decision the Court said: "A change in form, proportions or degree, doing substantially the same thing in the same way by substantially the same means, with better results, is not such invention as will sustain a patent"; and on its own behalf it held "that to sustain the appellee's (Minerals Separation) patent would be to give the owners thereof a monopoly of that which others had discovered."

There are two courses yet open to Minerals Separation before it may consider its case finally lost. It may seek a review of the decision by the U. S. Supreme Court directly or it may endeavor to get a different decision in another circuit of the Court of Appeals and if successful, bring the case before the Supreme Court for final judgment. Either course is beset with very great difficulties. It may be expected, however, that Minerals Separation will not accept defeat until it has exhausted every possibility of carrying the case to the highest court, just as it has done successfully in its Australian litigation. It is equally true that it will find ready adversaries along the way, eager to break the monopoly which undoubtedly has deterred some big operators from openly adopting flotation.

However, with the patent statutes once definitely and finally declared, we believe the flotation process will be widely used in this country and prove especially valuable in reducing mineral waste.

---

## High-Frequency Spectra of Elements and the Structure of Matter

It is well known that when a substance, which for definiteness may be a simple elementary substance, such as aluminium, is powerfully heated, it emits radiation with a certain range of variation in regard to frequency or wave-length. Such wave-lengths may extend from about 0.1 μ to 30 μ or more, the symbol μ designating a micron, or the millionth of a meter. The range of the visible spectrum is known to be roughly from 0.4 μ to 0.8 μ.

When an elementary substance is supported in a vacuum-tube and is made a target for electric discharges, the substance emits X-rays. For a long time it was supposed that X-rays had no wave-length; but recent researches have shown that they consist of two types of radiation, one of which is irregular or non-rhythmic, so as to have no wave-length; while the other is regular and rhythmic, possessing a wave-length. This X-ray wave-length is, however, very much shorter than that of the ordinary incandescence spectrum. It may range from 60 μμ to 800 μμ where the symbol μμ is a micro-micron, or the millionth of a millionth of a meter. It is only possible, at present, to measure these extraordinarily small wave-lengths, by means of reflecting mirrors of molecular type. That is to say, the polished reflectors of ordinary light are far too coarse-grained, and crystalline surfaces of natural cleavage have to be used.

In recent numbers of the Philosophical Magazine, Mr. H. G. J. Moseley has described some important experimental researches on the frequencies and wave-lengths of X-rays emitted from targets of different substances employed successively as the cathode in an X-ray tube. The generated X-rays, after passing through a small slit, are allowed to fall upon the surface of a crystalline reflector. The incident beam of X-rays emerges from the crystalline surface in certain definite directions, when the angle of incidence is just right for rays from the particular substance under investigation. The reflected beam is caught on a photographically sensitive plate, and leaves a record line on its surface after the plate has been developed.

The whole experimental system has ordinarily to be worked in vacuo, as the air would absorb the faint reflected beam.

It is shown that each elementary substance has a definite X-ray frequency of emission, such that, if the square-root of the frequency is taken as abscissas, the various elementary substances plot along a straight line in order of atomic weights. Thus, every element from aluminium to gold, possesses a certain whole number N, which determines its X-ray spectrum, and which Mr. Moseley calls the "atomic number" of the element. It is noticeable that whereas the atomic weight of an element is not a whole number or integer, the X-ray atomic number is claimed to be in all cases a simple integer, commencing with 13 for aluminium, and ending with 79 for gold, with only three gaps, which are suggested to belong to elements as yet undiscovered. Moreover, the atomic number N is identified with the number of positive units of electricity in the atomic nucleus of the atom. The order of succession of the atomic numbers is, with a few exceptions, the same as the order of atomic weights, and the exceptions appear to exist at points in the series where the chemical properties of the elements disagree with the order of atomic weights. Expressed in another way the squares of the successive numbers are proportional to the X-ray spectrum frequencies of the various elementary substances.

The observations also indicate that in the elements investigated, the angular momentum of an electron in any elementary atom is the same. That is, the product of the square of the orbital radius of an electron, into its angular velocity about the center of the atom, is the same for all electrons and atoms. If this result can be verified, it will constitute a remarkable generalization concerning the constitution of matter. It supports the hypothesis that each negative electron pursues an orbit about the positive atomic nucleus, and is held in equilibrium at that orbital radius where the inwardly directed electric attraction balances the outwardly directed contrifugal force. The attractive force on each planetary electron would thus be a purely electrostatic force, enormously greater than that of gravitation; while the repulsive force would be a purely magnetic force, not differing except in magnitude from the force of inertia in the world immediately perceived by the senses.

There is thus presented experimental evidence for the belief that the atoms of different elementary chemical substances differ fundamentally, and in the most simple order of classification, by the number of positive electrons forming their respective nuclei. Each atom may be regarded as a sun-and-planet microcosmic system, in which the positive nucleus corresponds to the sun and the gyrating negative electrons to the planets. Whereas in the cosmic universe, planets differ in size and in angular momentum, in the microcosmic or atomic universe, planets all have the same size, and also the same angular momentum. Oscillations in the orbital paths of electrons due to cathode-ray impacts, give rise to the high-frequency spectrum oscillations of the atom; whereas oscillations between molecules produce the lower-frequency spectrum oscillations that give us the colors of the rainbow.

## A Suggestion of a New Method for Determining the Temperature of Ingots

*To the Editor of Metallurgical & Chemical Engineering:*

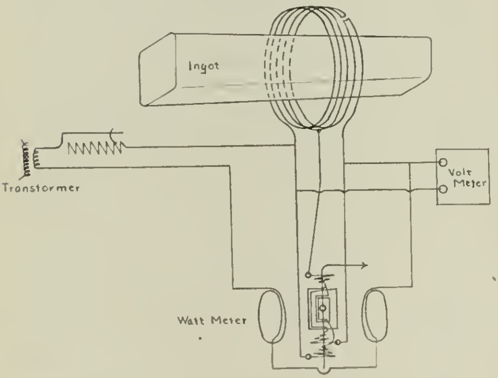
SIR:—Considerable saving in power required to roll steel and other meals could be made if a suitable means were devised to control the temperature of the object to be rolled. No doubt improved quality of the finished metal might also result if uniform methods could be practised.

In the quenching of steel objects such as tools, permanent magnet forms, etc., valuable data might be obtained if the time-temperature curve were readily obtainable.

The value of an idea which might result in the accomplishment of satisfactory temperature determination, is the excuse for these remarks.

The determination of temperature of a steel ingot, for instance, is accomplished best at present probably by the use of thermocouples, though in certain cases it might be possible to use the electrical resistance method.

Using the thermocouple it is practicable to apply same to the ingot surface only, but this surface is covered with an oxide coating more or less variable in thickness so that the indications produced by the thermocouple are hard to correct for average temperatures within the ingot. Certain methods of heating ingots would also influence the correction factor to be applied to the surface indications; the centre of the ingot may or may not be hotter than the surface. Considerable time is required when a thermocouple is used due to its low heat conductivity as a rule. Heat is also abstracted from the place of contact.



ELECTRIC METHOD FOR DETERMINING TEMPERATURE OF INGOTS

The resistance method requires contacts with the heated object, which are difficult to obtain as desired; the method is slow also therefor.

Electrical resistance, magnetic hysteresis and permeability are functions of the temperature. Suppose a coil be provided (as indicated in the sketch), through which an alternating current was caused to flow, the e.m.f., wave form, frequency, etc., being maintained constant. The ingot whose temperature was required might be introduced into the field of this coil and the sum of the eddy current and hysteresis energy losses read from the wattmeter. The $I^2R$ loss of the coil could be automatically subtracted from the total energy loss so that the wattmeter would indicate energy manifestations within the ingot only. A differential wattmeter might be used as indicated, and this procedure should obviate the error which would otherwise result due to resistance change of the coil with heat.

The indication of the wattmeter would be instantaneous and could be readily obtained in temperature figures with a suitable calibration curve.

The calibration curve might be absolute or empirical, but certainly it would obtain only for a given ingot of fixed size and practically fixed composition. The position of the coil with respect to the ingot would also require to be practically fixed.

This method would require no contacts with the heated object other than those of the charging machine or manipulating device ordinarily used.

RECORD OF ONE YEA' COMMERCIAL OPERATION

I am enclosing a blue print showing a recapitulation of a year's log sheet from an 800-kw gas power plant operating on bituminous coal that costs $3.50 per ton. By checking the various items in this table carefully you will note that with uniform load factor somewhere near the capacity of the plant and when in twenty-four hour operation power could be developed at a very low figure in such a plant. The cost data in this recapitulation are carefully kept, and all of the expenses, including fixed charges, incident to the operation of the plant, are figured in. I believe that such equipment as this could be advantageously used in the electrochemical industry. I note from the discussion of the various papers that there is sufficient waste heat from the reverbatory furnaces in these plants to furnish all the steam necessary for heating purposes. Considerable heat can also be recovered from the waste from the gas engines if the waste from the furnaces is not sufficient.

Regarding Mr. Vom Baur's comments on the possibility of oil engines to operate on Mexican fuel oil, I will say that Diesel engines in Texas will not operate successfully on this fuel. This can be verified on the ground by any one interested in the subject. There are probably more Diesel engines in Texas than in any other part of this country and they are operating on high-grade oils.

R. M. CHATTERTON.

Smith Gas Power Co., Lexington, Ohio.

### The Heat Treatment of Steel—Results Obtained by Spring Makers and Steel Works Treatment

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—The question of heat treatment is now attracting the attention of producer and consumer to a degree almost unparalleled in the field of steel manufacture. In order to get satisfactory results, it must be approached in a practical and scientific manner, because if the consumer carries his specifications to an extreme extent, it will be almost impossible to secure steel from the producers.

An extensive research was carried out by the author in 1910 upon a carload of steel that had been rejected by a prominent spring manufacturer, who claimed that it could not be "tempered" even in water. Upon receipt of the carload of steel, an analysis was made for carbon which was found by combustion to be 0.95.

The question arose at once whether there was some hidden cause, why the steel could not be tempered as the spring makers wrongly called it, whether there was something wrong with their methods or something wrong with the combustion apparatus and supplies used, whereby high-carbon results were being obtained. The last question was attacked first and it was finally found, by running checks upon known standards, that the apparatus, supplies and results obtained were correct.

The next problem was to answer the claim of the spring maker that this steel could not be "tempered," or rather hardened, as it should be called, in water. Several pieces were selected at random from the car, heated in a mill furnace and hardened by two methods in a bosh of water, both lots of steel being heated to a like degree. In the first method the steel was quenched as soon as it was drawn from the furnace, in the second method the steel was allowed to cool to a point slightly over the recalescence point and then quenched, this being done to approach as nearly as possible the method followed in some manufacturing plants.

In both cases by dropping the steel upon the mill tracks, it was found to be as brittle as glass. The first lot quenched had an extremely fine grain, and the second had a coarse structure on account of the crystals having time to grow, before the steel was quenched. This answered the statement that the steel would not harden in water.

Upon this report being turned into the office, it was put up to the writer to find out just what was wrong. It must be taken into consideration that this steel was an ordinary carbon steel and, therefore, any kind of treatment was good enough, from the viewpoint of the manufacturers.

The heat numbers shown in table 1 were selected for the extended research, several billets being rolled into $1\frac{3}{4}$ x $\frac{1}{4}$ square edge flats.

TABLE 1—HEATS SELECTED

| Heat Nos. | Shippers Carbon | Works Analysis |
|---|---|---|
| 1490 | 0.96 | 1.09 |
| 1493 | 0.92 | 0.90 |
| 1524 | 0.96 | 0.94 |
| 1527 | 1.00 | 1.05 |
| 1538 | 1.02 | 1.00 |
| 1540 | 1.12 | 0.94 |
| 1541 | 1.06 | 1.04 |
| 1550 | 0.90 | 0.90 |
| 2565 | 1.08 | 1.03 |
| 2582 | 0.90 | 0.90 |

Bars selected were marked Lot Nos. 1 and 2. Bars from Lot No. 1 were nicked on one end in order to make a fracture after tempering. In order that the test should be a practical one, a rolling-mill furnace was selected after it had cooled down from its day's run. The temperature was then brought up to the desired point, the bars put in and each one heated uniformly and quenched in oil, the furnace was then cooled down and the bars placed back and the temper drawn, until the oil just flashed.

It must be taken into consideration that this method was followed in order to duplicate as closely as possible the spring makers' methods, then employed.

These bars were then tested in an oil hydraulic spring tester having an upward thrust, they being placed on two knife edges on tester tables, the pressure being taken up in the center by means of another knife edge in head of tester. In order to get a sensitive measure of the permanent set, the bars had been formed with a camber of one-half inch.

Lot No. 1 was tested at a modulus of rupture of 130,000 lbs.; Lot No. 2, 140,000 lbs.

TABLE 15—RESULTS OF TESTS
130,000 lbs.

| Heat | Lot | Permanent Set | Fracture | Heat | Lot | Remarks |
|---|---|---|---|---|---|---|
| 1490 | One | None | | 1490 | Two | Lot No. |
| 1493 | " | " | All | 1493 | " | one heat |
| 1524 | " | " | | 1524 | " | 2565. |
| 1527 | " | " | uniform, | 1527 | " | carried |
| 1538 | " | " | | 1538 | " | up to a |
| 1540 | " | " | fine | 1540 | " | modulus |
| 1541 | " | " | | 1541 | " | of 150,000 |
| 1550 | " | " | and | 1550 | " | Permanent |
| 2565 | " | " | | 2565 | " | set 1/16" |
| 2582 | " | " | silky | 2582 | " | |

Loads applied 5 times

Feeling safe after such a test, rollings were made from these heats and shipped. An awful holler was raised, it being emphatically stated that this steel could not be tempered by the regular shop methods and that a special treatment had to be designed.

After these reports were turned in, it was decided that the trouble was a case of six on one side and half a dozen on the other, both the steel and spring manufacturers being at fault.

The conclusion drawn from the research was that in order to get satisfactory results from any type of steel, carbon or alloy, it was necessary to give the steel a proper treatment. Also that the method used for manufacturing the steel leaves its effect upon the steel so produced.

WILLIAM D. MAINWARING.

## The Western Metallurgical Field

### Carnotite Concentrators for Colorado

Essentially two methods of concentrating carnotite ores have been developed as the result of experimentation during the past few years. Ordinary methods of concentration based on difference in specific gravity of minerals will not suffice, for the uranium-vanadium mineral exists as a thin coating or sand grains and produces a slime or powder when removed from the gangue. Hence special methods of separation and concentration have been devised—both wet and dry. The general principle of these methods has been made public by the Bureau of Mines in Bulletin 70[1], and details of a wet process also have been published in this journal.[2]

Until recently, however, no attempt to concentrate these ores has been made on a commercial scale, although the economic reasons for so doing have always been recognized. The Standard Chemical Company, of Canonsburg, Pa., is to be the first in the

---

[1] See this journal February, 1914, page 89.

[2] Article by Siegfried Fischer, October, 1913, page 586.

Colorado district to build concentrating plants. This company owns a large number of claims and is probably the largest single producer of carnotite in this country. It has figured prominently in the "radium hearings" before congressional committees, and has been concerned over the proposal of the Government to produce radium; but with the Government's position made clear by Dr. Joseph A. Holmes,[3] undue anxiety on this score may now be allayed.

It is reported that the Standard company will erect several concentrating plants at different points in southwestern Colorado: one near Naturita, 60 miles west of Telluride; a second in the East Paradox district, and a third in the McIntyre field. A fourth may be built in Utah to handle ore from the southeastern part of that state. The immediate construction of the first mentioned is assured, and machinery for it has been purchased.

No announcement has been made as to the details of the process to be used, but the general principles can be surmised from the references given. It is known, however, that Mr. Warren F. Bleecker, now on the metallurgical staff of the company, developed concentrating processes for carnotite while making independent researches on uranium and vanadium ores in Colorado before taking his present position, and it is probable that his methods will be adopted on a commercial scale in the new plants.

### Bureau of Mines

The third annual report of the Director of the Bureau of Mines deals with the aims and objects of the Bureau, outlines its needs and gives a summary of work accomplished in its various departments. Some of the items are of special interest to the metallurgical industry.

During the fiscal year 1913 a study was made of milling methods in the lead-zinc districts of Missouri, Oklahoma, Arkansas, Wisconsin and Illinois. The investigation showed the possibility of practicable savings of ore now wasted. This work is to be continued and published in a bulletin.

The electric smelting of ores was under investigation at Pittsburgh. One problem studied was the possibility of using crude oil as a reducing agent, while another was the smelting of copper concentrates. In non-ferrous metallurgy the following points were considered: the possibility of recovering the iron in slag; of producing ferro-silicon from slags; of recovering sulphur from sulphide ores, and of discovering some suitable collector other than lead and copper for precious metals in smelting practice.

A study of sampling and assaying methods was under way during the year. This included the sampling of ores and metals, molten and solid alloys, charges in the furnace, and solid materials. It is hoped that the investigation will give methods that can be accepted as standard by producers and operators.

The work on smelter fumes and gases was conducted at San Francisco. This had special reference to the recovery of valuable constituents of fumes which are now wasted. New uses have been sought for sulphur, arsenic, bismuth, selenium and tellurium. Formal cooperation with the Bureau in advancing the work has been given by the Anaconda smelter in Montana and the Selby in California. A special report on the methods now in use or being tested for prevention of damage by smelter smoke is to be made by Mr. C. H. Fulton.

Other interesting studies have been under way in reduction of mineral waste, prevention of losses in making non-ferrous alloys, utilization of domestic fuller's earth, silica and minerals used in the making of refractories.

### Societies and Organizations

The Utah members of the American Institute of Mining Engineers have been organizing a local section of the parent body, preparatory to formulating plans for entertainment of the Institute at the meeting in Salt Lake City in August. Mr. R. C. Gemmel, manager of the Utah Copper Co., and Mr. Ernest Gayford, of the General Engineering Co., have been active in the work. The Utah engineers have asked the Nevada members of the Institute to join in the organization, which may be known as the Utah-Nevada section, provided the Nevada members acquiesce. The Salt Lake meeting of the Institute promises to be as successful as was the Butte meeting, and it is certain that Utah hospitality will make the affair most pleasant as well as profitable.

The International Engineering Congress has announced the topics under which the section on Mechanical Engineering will group the papers presented. Many of these topics are of direct interest to the metallurgical fraternity, as they deal with metal working, industrial management, power plants, etc. At present the Congress has received enrollments and subscriptions from 42 foreign countries. The subscriptions from the membership of the five American engineering societies, under whose auspices the Congress is held, is not so gratifying, and amounts to only 3.7 per cent of the total subscriptions. Procrastination on the part of American engineers is handicapping the work of the Congress, and they are urged to subscribe at an early date.

### Flotation Litigation

In a recent circular to stockholders, the Ore Concentration Co., Ltd. (Elmore process), makes the following statement relative to its action for infringemen against the Sulphide Corporation, Ltd., in New South Wales.

"The judgment, which was delivered on the 6th of March, is very disappointing in one respect, inasmuch as the process as carried out by the defendants is held not to be an infringement of the patent sued under. On the other hand, it is satisfactory that a certificate of validity of this patent will be granted to us by the Court, and that all the alleged anticipations set up against it by the defendants have been swept aside. The position therefore at the present moment is that we have not proved infringement by the defendants in the above case, but we have established that our own patent is good and valid."

### Anaconda-International Consolidation

Announcement is made that the Anaconda Copper Mining Co. has purchased the assets and business of the International Smelting & Refining Co. The International was organized several years ago, and its technical operations have been directed by men formerly in the employ of the Anaconda company. It has a lead and copper smelter at Tooele, Utah, and a refinery near Chicago. Anaconda company capitalists have been heavily interested in the International company, and the consolidation causes little surprise in view of the close arrangements formerly existing between the two companies.

### Company Reports

Operations at the plant of the **Old Dominion Copper Mining & Smelting Co.**, Arizona, during 1913, were carried on under adverse conditions, due mainly to congestion in the mining department caused by enlarging underground stations and cutting skip pockets. The construction of a new concentrator and the experiments that were carried on during the year made economical operation of the old mill a difficult matter. The new mill probably will not be in operation before August next.

---

[3] See this Journal May, 1914, page 331

| Ore Extraction: | Dry Tons | Average Copper, Per Cent |
|---|---|---|
| Smelting ore | 120,257 | 6.85 |
| Concentrating ore | 47,785 | 3.56 |
| Silica lining | 1,919 | 3.37 |
| Total and average | 169,961 | 5.88 |

| Concentration: | Dry Tons | Per Cent Copper | Cost Per Ton |
|---|---|---|---|
| Company ore | 47,972 | 3.56 | ...... |
| Custom ore | 102,231 | 3.76 | ...... |
| Total and average | 150,203 | 3.70 | $0.878 |

Concentrating cost in 1912 was only $0.753 per ton. The increase in 1913 was due chiefly to abnormally heavy repairs in the mill, and reduced capacity caused by construction work. Experiments on flotation by the Minerals Separation process have been under way to determine the results that may be obtained by thus treating fine slime on which a heavy loss has been sustained in the past.

| Smelting and Converting: | |
|---|---|
| Tons new charge smelted | 300,926 |
| Cost per ton | $2.629 |

The cost was higher than in 1912 ($2.304) due to increased coke consumption, higher wages and extraordinary improvements. The smelting of flue dust was discontinued for three months, but was resumed when the furnaces showed no improvement in running without this material in the charge.

| | |
|---|---|
| Pounds blister copper produced | 30,811,141 |
| Pounds fine copper produced | 30,572,863 |
| Cost converting per ton fine copper | $9.19 |

The old acid-lined converters have been replaced by the Great Falls type of basic-lined converter, and the results are satisfactory. The cost of converting in 1912 was $9.45 per ton of fine copper. The saving effected in 1913 was derived mainly from the decreased cost of relining, which fell from $2.23 per ton of copper in 1912 to $0.25 in 1913. The cost of improvements amounting to $24,732 is included in the cost for 1913. The total cost of producing fine copper was 9.70 cents per pound.

The annual report of the Miami Copper Co., Arizona, for 1913, contains the following items of metallurgical interest. Experimental work conducted in one of the six sections of the mill has shown that the plant can be remodelled to handle at least 4000 tons of ore per day. Various mill improvements resulted in a lower cost of treatment, which is given below:

| | Per Ton |
|---|---|
| Crushing | $0.20806 |
| Concentrating | 0.18852 |
| Handling tailing and concentrates | 0.05880 |
| Water for concentrating | 0.08553 |
| Betterments | 0.03134 |
| Total | $0.57225 |

The results of milling operations for the year were as follows:

| | | |
|---|---|---|
| Ore milled | 1,058,784 tons, | 2.30% copper |
| Concentrates produced | 45,410 tons, | 38.09% copper |
| Copper in concentrates | 34,597,568 pounds | |
| Copper per ton ore | 32.68 pounds | |
| Mill extraction | 71.06% | |

The cost of refined copper in concentrates on board cars at Miami, based on net smelter returns, was 7.9 cents per pound.

The company has developed about 6,000,000 tons of mixed oxide and sulphide ore, for which it hopes to develop a combination concentration and leaching process.

The 24th annual report of the Wallaroo and Moonta Mining & Smelting Co., Ltd., South Australia, covers the operations during the year 1913. The report of the general manager, Mr. H. Lipson Hancock, states that the results of the flotation process at the concentrators has justified the expenditure made therefor, and is enabling the company to make a higher recovery of copper. The treatment of the slime tailing dumps at the Moonta mines, by leaching and precipitating, has been improved through a system of regular plowing which expedites oxidation of the copper minerals and yields a liquor richer in copper. Similar work at the Wallaroo mines has been discontinued in favor of flotation. One blast furnace in operation for 308½ days smelted 90,190 tons of charge. The output for the year was 7112 tons refined copper, 2161 ounces fine gold, and 1000 ounces silver 996 fine. The acid works produced 5602 tons sulphuric acid.

## The Iron and Steel Market

While the stagnation in the iron and steel market was not greatly accentuated in May, there being, indeed, very little margin left for such a change, the dissatisfaction of the trade with existing conditions was greatly increased, because it became high time for an improvement to set in. The market lost ground constantly throughout 1913, and towards the close of the year a period of inaction lasting several months was indicated. Somewhat to the surprise of the trade a rather substantial revival occurred in January, and the recuperative power thus shown gave the trade much encouragement, so that it expected, after perhaps a lull of a month or two, a prolonged and marked improvement, particularly as the advent of spring normally brings increased consumptive requirements. As week after week has passed with the market showing somewhat increased stagnation, instead of marked improvement, the trade has become much depressed.

The output of finished steel in May has not been more than about 55 per cent. capacity, against about 65 per cent. in April, the highest rate this year having been close to 75 per cent., early in March.

Steel bookings during May have probably averaged somewhat less than 50 per cent. of capacity, and were at approximately a stationary rate during the month.

As in April, the course of steel prices has been downward, though not markedly so. Prices were already so near the cost of production, taking cognizance of depreciation and fixed charges and the increase in cost due to light operation, that all declines have met with stubborn resistance.

Towards the close of May a change occurred in sentiment, the trade becoming rather hopeful that some slight improvement at least would occur before midsummer, on the theory that stocks were altogether depleted throughout the country, with actual ultimate consumption at a rate in excess of the current mill shipments. Hopes for good business in the second half of the year were augmented by the extremely favorable crop outlook, reinforced by evidences that the railroads were placing themselves in better position by the practice of severe economy.

Wage reductions, seriously discussed by independent mills in April as a probable necessity should conditions not improve within a short time, are still under consideration, but the positive attitude the United States Steel Corporation is known to have assumed against any wage reductions is likely to act as a deterrent influence, the independents fearing that they would be placed in an embarrassing position.

### Pig Iron

May saw a decided revival in interest in the pig iron market. Several steel interests purchased basic pig iron for third quarter, and in one or two instances for the entire half year, while there was a marked increase in sales of foundry iron in small lots. In some quarters the increased activity of pig iron has been held to presage a general improvement in the iron and steel industry, but it will do no harm to reflect upon the fact that last summer witnessed a decided improvement in the pig iron market without any improvement in the steel market. What occurred then was that pig iron buyers put off their purchases until many were forced into the market at the same time, and, while their purchases advanced prices slightly, the market began to weaken again as soon as the buying was over, and eventually reached a lower level than ever. About the beginning of May it was quietly announced that Lake Superior ores would be sold for 1914 delivery at the 1912 schedule, involving reductions from 1913 of 55 cents on non-Bessemer and 65 cents on Bessemer ores, the announced prices being: Old range Bessemer, $3.75; old range non-Bessemer, $3.05; Mesabi Bessemer, $3.50; Mesabi non-Bessemer, $2.85, on Lake Erie docks. It is since rumored that sales have been made at 15 to 20 cents under the announced prices, but irrespective of prices the sales have not been large, and the "opening" even though delayed has been quite different from openings in most previous years, when large tonnages were placed under contract in a few days. The decline in ore from 1913 to 1914 is held not to necessitate or permit any decline in pig iron, it being maintained that the pig iron market in its declines had already discounted the reduction in ore, which was fully expected even before the close of 1913. Connellsville coke has weakened somewhat, there being a few contracts made for delivery after July 1 at well under $2, the price to which the majority of operators have steadfastly adhered for months. The pig iron market stands quotable as follows: No. 2 foundry, f o.b. Birmingham, $10.50; delivered Philadelphia, $14.75 to $15; f.o.b. furnace, Buffalo, $13; delivered Cleveland, $14.25; f.o.b. furnace, Chicago, $14; at valley furnaces (90 cents higher delivered Pittsburgh), Bessemer, $14; basic, $13; No. 2 foundry and malleable, $13; forge, $12.50 to $12.75.

### Steel

The market for billets, sheet bars and rods was quiet throughout the month, there being no prompt requirements to be filled and very little interest in deliveries after July 1, to which date consumers seemed to be well covered. Market prices are largely nominal, as follows: Billets, $20; sheet bars, $21; rods, $26, at maker's mill, Pittsburgh or Youngstown.

### Finished Steel

Slight weakening occurred during the month in the majority of products. Prices named below are f.o.b Pittsburgh unless otherwise noted:

Rails, standard sections, 1.25c. for Bessemer and 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.12½c.

Steel bars, 1.12½c. base.

Shapes, 1.15c.

Iron bars, 1.30c., Pittsburgh; 1.22½c., Philadelphia; 1.10c., Chicago.

Wire nails, $1.55 to $1.60, base; plain wire, 1.35c. to 1.40c.

Sheets, blue annealed, 10 gage, 1.35c.; black, 28 gage, 1.85c.; galvanized, 28 gage, 2.80c.; painted corrugated, 28 gage, 2.05c.; galvanized corrugated, 28 gage, 2.85c.

Merchant steel pipe, ¾ to 3 in., 80 per cent. off list.

Steel boiler tubes, 3½ to 4½ in., 72 per cent. off list.

Standard railroad spikes, 1.40c., Pittsburgh, 1.50c., Chicago.

Structural rivets, 1.60c.; boiler rivets, 1.70c.

Cold rolled shafting, 66 per cent. off list.

## American Electrochemical Society

The twenty-sixth general meeting of the American Electrochemical Society will be held at Niagara Falls on Thursday, Friday and Saturday, Oct. 1, 2 and 3, 1914. A local committee has been formed with Mr. L. E. Saunders as chairman.

Mr. F. A. Lidbury, works manager of the Oldbury Electrochemical Company, of Niagara Falls, is the president of the society. Dr. Joseph W. Richards, Lehigh University, Bethlehem, Pa., is the secretary.

## BRITISH IRON AND STEEL INSTITUTE

The annual meeting of the Iron and Steel Institute was held in London on May 7th and 8th, 1914. Annual reports of officers were presented and the president-elect, Mr. Adolphe Greiner, was introduced into office. The Bessemer gold medal for 1914 was presented to Mr. Edward Riley. Following is the list of papers on the program:

The Forms in Which Sulphides May Exist in Steel Ingots. By J. O. Arnold and G. R. Bolsover.

Experiments on Allotropy of Iron (Behaviour of Ferro-Magnetic Mixtures; Dilatation of Pure Iron). By C. Benedicks.

Recent Developments of the Iron and Steel Industry in India. By A. Bose.

The Recrystallization of Deformed Iron. By C. Chappell.

The Hardening of Iron and Its Alloys. By C. A. Edwards and H. C. H. Carpenter.

Influence of Molybdenum Upon the Corrodibility of Steel. By J. N. Friend and C. W. Marshall.

Note on a Curious Case of Decarburization During the Hardening of Steel Dies. By H. C. Greenwood.

The Magnetic and Mechanical Properties of Manganese Steels. By Sir Robert A. Hadfield and B. Hopkinson.

Case-Hardening. By H. L. Heathcote.

Failures of Heavy Boiler Shell Plates. By S. A. Houghton.

Production of Steel Direct from the Ore. By E. Humbert and A. Hethey.

Theory of Hardening. By A. McCance.

The Colorimetric Estimation of Sulphur in Pig Iron and Steels by Paper Impregnated with a Solution of Arsenious Anhydride in Hydrochloric Acid.

The Development of Dry Cleaning in Blast-Furnace Gas Purification. By F. Muller.

A New Reagent for Etching Mild Steel. By W. Rosenhain and J. L. Haughton.

Talbot Process at Witkowitz. By F. Schuster.

# Is There a Complex-Ore Problem?

## A Symposium on the Economics and Metallurgy of Mixed Base-Metal Sulphide Ores, Showing Present Status and Future Prospects of This Branch of Ore Treatment

In our May issue we published the first batch of replies received from a number of prominent metallurgists to an inquiry submitted to them in form of the following six questions:

1. Is there a "complex-ore problem," and what, in your opinion, constitutes a "complex" ore?
2. Would such ores be amenable to present methods in the hands of skilled operators, or is there a need for new methods of treatment?
3. Do you believe there are many mines now idle which could produce a considerable tonnage of such ore if suitable methods of treatment were known?
4. What element or quality of such ores makes them refractory to present processes?
5. What methods or processes do you regard as probable solutions of the problem (mechanical, hydrometallurgical, electrometallurgical)?
6. To what extent would microscopical examination of such ores be of material assistance in suggesting proper methods of treatment?

The following replies, since received, will be found equally interesting:

**Stuart Croasdale.**—If we are to adhere to the usual definition of an ore, as a mineral or group of minerals which can be worked at a profit, many of the so-called complex-ore bodies do not exist. If we are to consider as complex-ore, what one engineer has aptly termed a "mineral aggregate," or a group of minerals which cannot be worked at a profit, individually or collectively, by existing methods or under existing conditions, but which have an assumed value based on the gross market value of the merchantable metals contained therein, then the field might be broadened even to the sands of the sea.

However, placing both ore and "mineral aggregate" containing from two to five of the more common merchantable metals under the term of complex-ore, I think the available quantity of this material is greatly overestimated. Improved methods of ore treatment may increase the number of producing mines to some extent, but my experience has been, in examining properties of this character, that the ore bodies frequently are too small to justify the erection and operation of a reduction plant, and too low-grade to ship crude to a custom plant, except in very favored districts. When the "ore in sight" will not pay, or more than pay, for the property itself and a suitable metallurgical plant, the problem becomes very simple. On the other hand, we all know there is a proportionate number of good properties containing large tonnages of complex ores, which are now standing idle or are operating at an unsatisfactory profit.

The only method now in use for the treatment of these ores is the mechanical concentration and separation of the minerals into marketable products for lead and zinc smelteries. This is necessarily done at the mines to avoid transportation of large quantities of gangue or worthless material. Losses occur at every turn. A typical recovery by this method in a Colorado mill, equipped with every type of device for concentration and preparation of commercial products, is as follows, based on the assays of crude ore and tailings: Gold, including free gold sold as bullion, 75.9 per cent; silver, 50.6 per cent; lead, 86.7 per cent; zinc, 58.6 per cent; copper, 55.0 per cent. Higher recoveries have to be sacrificed in order to maintain the products at a marketable grade. To the above losses must be added smelting charges, deductions, penalties, and metals in each product not paid for, the amount of which is appalling.

As an illustration of these losses, a recently published statement relating to a Montana property is significant. The ore can scarcely be called complex, for it was milled for zinc alone. Concentration and flotation are said to recover over 90 per cent of the minerals in the crude ore.

The zinc product contained 50 per cent zinc, 2.4 per cent lead, 0.5 per cent copper, 26.3 oz. silver and 0.05 oz. gold per ton, and cost $4.56 per ton to produce. This concentrate had a market value at the mill of $23.79 per ton. The gross value of the merchantable metals in this product, based on current quotations, was $80 per ton. Therefore, $56.21 per ton disappeared between the mill and consumer. This paid legitimate freight and smelting charges, of course, but mostly it represented metals not paid for which lie in the "residue" dumps at the zinc smelteries. How much greater are similar losses from complex ores?

Surely the present method of treatment is not all that can be desired, and it is scarcely conceivable that the cost of treatment in a more direct and refined metallurgical process, whatever it may be, will exceed the cost, plus the losses sustained by mechanical concentration and smelting.

The refractory character of complex ores is usually due to the chemical combination or physical arrangement of the minerals, and a microscopical examination of such ores will undoubtedly aid in an intelligent solution of the problem of their treatment.

No method of treatment can be considered the best for all complex ores. Each ore is a problem in itself. In some ores the minerals are coarsely crystalline and easily separated into comparatively clean high-grade products. Such ores, even, with the attendant losses, may be best adapted to mechanical concentration.

Other ores, when examined under the microscope, will reveal the minerals intimately associated in very small crystals, or perhaps in non-crystalline form, which, if separated, will involve so much loss in sliming and subsequent smelting that any form of mechanical separation would be condemned as impracticable if other processes were available.

In still other ores chemical combination exists in the form of double sulphides of the metals. The rational treatment of such ores certainly is not mechanical beyond the removal of a portion of the gangue, for no product can be made that will not involve a considerable loss in the form of a metal not paid for.

As stated before, only one method of treatment now exists—that of mechanical concentration and separation. The consulting engineer cannot recommend the installation of untried processes, no matter what his opinions and experimental results may be. His clients are like the gentleman from Ohio in the selection of horseflesh. They do not want a process that "has been" or "is to be." They want an "izzer." Therefore, the engineer wears the ore to a frazzle sending it through the interminable mechanical grooming and gets the best results he can with from 20 per cent to 30 per cent combined loss in tailings; his lead product containing 10 per cent unrecoverable zinc, his zinc product containing 10 per cent unrecoverable lead and more or less unrecoverable silver—all of which is, of course, unpaid for, if not penalized. If he can figure a profit when he is through, the system is installed; if not, the property stands idle awaiting a better method of treatment.

New processes cannot be put into operation by the discoverers nor by stock companies. They must be matured by companies that are working complex ores at a profit under existing methods and wish to improve their condition. This can be readily done by appropriations set aside from the earnings, which would virtually come from the properties themselves and not from the shareholders. In case of failure the loss of such an investment will not be felt, and in event of success the science of metallurgy, as well as the mine, will be amply rewarded.

If managing engineers in charge of properties of this kind would devote more time and energy to the development of new processes along lines best adapted to their ores, whether that process be hydrometallurgical, electrometallurgical or pyrometallurgical, I believe we would get out of the mechanical rut and make considerable advance in the treatment of complex ores.

There is a decided tendency in this direction at the present time among the large copper companies, particularly in connection with the treatment of low-grade porphyry ores, where the concentration and smelting losses are between 35 and 40 per cent, and also where large quantities of oxidized ores exist for which there has been no method of commercial treatment available. It is a pleasure to hear of the extension of this work to lead properties, and it is to be hoped that the complex ore properties will soon fall in line.

Much could be gained by combined and organized research among these respective types of properties, whereby a great deal of duplication of work and discouragement could be avoided. I know of a number of cases where work of this kind has been duplicated independently by engineers, and abandoned at the same point; whereas, if the second engineer could have profited by the experience of the first, both would have gained in coin and reputation, and a positive advance would have been made in metallurgy. If it is impossible, as some have said, to overcome professional jealousy in organized research of this kind, why not permit the Bureau of Mines to co-operate with and receive financial assistance from mining companies for such work in proportion to the benefits obtained, and thereby develop an "all star," impartial, national research staff.

Denver, Colo

**H. M. Parks.**—I have noted, in being around different mining camps, the general opinion which your questions suggest. Although the miner and prospector often speaks of the question as "the complex-ore problem," it seems to me that it might more properly be designated a phase of a "complex-ore problem." In other words the mixture of base-metal sulphides is an ore amenable to treatment by existing processes at a higher cost and treatment loss than one carrying only one valuable metal. Accordingly such a mixture, to be an ore in the present accepted meaning of the term, must have a total value considerably in excess of that needed when the value is all represented in one metal.

There certainly are millions of tons of rock containing metal values of such grade that they cannot now be treated at a profit, which may sometimes become profitable through the invention and improvement of processes, improvement of transportation facilities, etc. Many of our "complex ores" coming into this category have total metal values greater than other ores in the same locality which are being treated profitably for only one metal. That ore A worth $5 is being treated profitably, and ore B at the same mine worth $8 cannot be treated at profit, causes much comment; but when we consider that the valuable metal in A has but to be separated from the gangue, while several metals in B must also be separated from each other, we see that it is about as imperative to demand a new process to handle ore A as ore B.

We do need and probably always shall need improvement in our processes for treating ores, whether simple or complex; but it is probably true that the field is larger for treating the complex ores because the problem is more variable. The current impression that the "complex ore" is a present day metallurgical bug-a-boo is quite erroneous.

Corvallis, Ore.

**Robert H. Richards.**—Answering your questions briefly, will say that:

1.—A complex ore is one that is fine-grained, containing minerals that are difficult to separate, but which would have greatly increased value if separated.

2.—Some of these ores would yield to present processes skilfully applied, but others need new processes for their profitable treatment.

3.—It is reported that there are many mines now idle which could produce a considerable tonnage of ore if suitable treatment processes were known, but I am not in a position to know.

4.—Zinc seems to be the worst stumbling block in the metallurgy of complex ores.

5.—In my opinion all three of the types of processes mentioned—mechanical, hydrometallurgical, electrometallurgical—either separately or collectively, will be used in solving the problem.

6.—The use of the microscope would aid in determining the minerals present.

Boston, Mass.

**W. McA. Johnson.**—Metallurgically speaking an ore may be defined as mineralized material containing metal in sufficient amount and purity as to permit its profitable extraction. The terms "simple" and "complex" are relative and can best be illustrated by examples of each class. For instance, a simple ore is one that contains one metal constituent only, or so great a proportion of one metal as to permit of its extraction by a simple furnace treatment, the subordinate metal or metals, if present, not interfering with the extraction of the chief metal. This is exemplified by the ordinary sulphide or oxide ores of lead, of copper, or of zinc. When, however, the ore contains two or more metallic minerals in such a physical form as not to admit of separation by mechanical methods, and if the contained metals could not be easily extracted by present furnace methods, such an ore would be called a "complex ore." This might be exemplified by an intimate mixture of galena, blende and chalcopyrite or chalcocite—say 30 per cent zinc, 10 per cent lead, with or without a small percentage of copper; or copper 3 per cent and zinc 30 per cent. In cases of this kind the percentage of zinc present is too great to admit of smelting economically in the lead furnace, and the percentage of lead too great to permit of the profitable extraction of zinc in the ordinary retort furnace.

The question of the proper method of treating complex ores, such as those just quoted, constitutes the problem, and it is one that has remained unsolved in many instances.

Your second question, as to the amenability of complex ores to present day processes, provided skilled operators conducted the treatment, practically answers itself in the fact that there still remains the problem. Metallurgy is always progressing, and that which was good practice a few years ago is now considered bad practice; losses in slags and tailings permitted in the state of the art ten years ago would not now be allowed. For example, the porphyry copper ores of Utah could not have been treated profitably by processes of a decade ago, yet today they yield handsome returns—and even now the present practice is far from perfect, in that the tailings from the mechanical concentrators are stored up for future extraction by methods not yet devised or perfected. Hence an ore may be refractory today and easy to treat by improved or new processes tomorrow. The application of the laws of physical chemistry and commercial science, cemented by common sense and due diligence, will solve many a problem which heretofore has been too complex for a profitable solution. Eternal experimenting is the price of progress.

I decidedly do think that there is a need for new methods of treatment of the so-called complex zinciferous lead or copper ores, and I have devoted ten years of careful study and research to develop my present process, which I believe promises to settle many perplexing questions of metallurgical treatment.

As to possible idle mines which could produce a considerable tonnage of complex ores if suitable methods of treatment were available, I will say that I recently conducted a two-months' advertising campaign which had for its object the gaining of information as to the need of a process which would extract practically all of the metal content of zinciferous lead or copper (or both) ores, and my files are filled with letters from all parts of the country. In most of these letters the ore mentioned is not now being marketed, although the total combined metal values show a good working margin. Whether these deposits represent the "millions of tons" referred to in your letter I have not as yet computed, but they appear to be quite extensive and in need of some process which will render their treatment commercially profitable.

The Johnson electric furnace process, as developed to its present state of efficiency, can extract from ores practically all of the contained zinc, lead, copper and precious metals, in one smelting operation, thus avoiding the wasteful process of concentration in which there is an unavoidable and large loss of mineral in the tailings, and eliminating the subsequent heavy penalty charge for treatment by the smelter of the large percentage of zinc usually present. Moreover if one considers that during the past year the value of the zinc which was thrown away in the slags of American smelting furnaces aggregated $30,000,000 (equivalent to two-thirds the output of zinc in the United States for that year), the great importance of a process which will save the zinc in these complex ores is manifest. This question is answered in the strong affirmative by the contents of the many letters received.

In reply to question 4, I should say that the cause of the refractoriness of these complex ores is chiefly the presence of a high percentage of zinc, the ores being so constituted physically as not to be amenable to separation of the component minerals by mechanical treatment.

I consider that the Johnson electric furnace process will solve most of the problems now under consideration; and while there may be future progress in the mechanical and hydrometallurgical fields, their application for the treatment of zinc ores does not seem to me to be promising of satisfactory results.

Your final question as to whether or not a microscopical examination of complex ores would be of material assistance in suggesting proper methods of treatment, is one of interest; but the application would be of value chiefly as an aid to determine the proper methods of mechanical concentration. If the ore were rich enough it could be smelted direct in the electric furnace, but a case might arise in which it would be desirable to concentrate the ore (even though some of the mineral content be lost) prior to smelting. As a general rule the details of the electric furnace treatment have to be determined for each individual ore, if wholly satisfactory results are to be attained.

Hartford, Conn.

**Francis A. Thomson.**—1.—There is, I think, in a limited sense a "complex-ore problem," but the problem is less serious and not as general as is commonly supposed.

By a "complex ore" I mean an ore containing sulphides of copper, zinc and lead in sufficient quantities to justify the recovery of all three metals, with of course the usual accompaniment of gold and silver.

2.—Such ores are in part amenable to treatment by present processes when properly conducted. This is more true of the recovery of the copper and lead than of the zinc. There is a moderate demand for a process which will permit more complete recovery of all three metals than is now possible.

3.—To my knowledge there are very few mines lying idle because of the complexity of their ores. I have had occasion to examine many mines, which were claimed to be idle from this cause, but have never yet found the claim to be true. Quantity or value of ore was lacking in every case.

It is my experience that this claim is often the means by which ignorant or deceitful persons impose "fake processes" and fraudulent promotions upon the public.

4.—There are mainly three causes of the refractoriness of complex ores:

a. The intimate intermixture of the sulphides mentioned.
b. The lack of difference in specific gravity between chalcopyrite and sphalerite.
c. The volatility and ready oxidability of zinc.

5.—For (a) and (b) in the preceding classification, magnetic or electrostatic separation seems to promise best. Flotation also may come to have an important place.

For (c) electric smelting would seem to have possibilities in view of the ease of control of furnace atmosphere and temperature. Of course, proposals for a sulphatizing roast of the Ziervogel type, with subsequent leaching with water, or an oxidizing roast with a sulphuric acid leach, the acid being made from the gases of the roasting operation, are always with us and may some day displace igneous concentration, but this is doubtful.

In general the progress of the future will be like that of the past—slow improvements step by step rather than sudden changes of a revolutionary character.

6.—Microscopic examination of any ore as a preliminary to devising a treatment scheme is exceedingly valuable, and all of my students are being trained to appreciate its value and to make use of the microscope daily for problems of this kind.

Pullman, Wash.

**Lewis B. Skinner.**—I would say, in the first place, that what is generally termed a "complex ore" is a mixture of the various metal sulphides such as zinc, lead and iron. Such ores may or may not contain gold and silver, but usually do. There is usually some gangue with these sulphides, which is commonly of a silicious nature, but may be lime, dolomite or barytes.

In answer to the second part of the question, would say that there certainly is a complex-ore problem. There is also a gold-ore problem, a lead-smelting-ore problem and, in fact, problems in the handling of all ores. Every one who is trying to work as efficiently as possible is trying to cut down the manufacturing costs of all of the metals. Since complex ores usually contain the metal zinc as the most valuable constituent, I refer more particularly to zinc itself when referring to complex ores.

We hear a great deal about the terrible loss that obtains in reducing metallic zinc. This is no worse than that obtaining in the production of other metals, i.e., putting them into merchantable shape. Were we without any processes at all for the manufacture of zinc or spelter, we would then have a real problem; but we are not without methods, which, while not as efficient as any one desires, are still able to compete against a given market and turn out a sufficient supply of metal.

2.—Usually the first step in the production of any of the metals is ore-dressing. The ores as mined are of too low a grade to be handled directly in any smelting operation. It is not a fact that poor methods make the losses high, but that the handling of ore-dressing methods is deplorable. There are only a few plants practicing ore-dressing that do so with the idea of getting every pound of available material. It is usually only a question of whether the mill, taking its own mine ore, is paying a profit. If it does not, the mine is blamed for it. If it does, all are satisfied. The poor quality of mill operation is no doubt responsible for the notion that there is a complex-ore problem. To offset this many experimenters have undertaken to get up a new mode of procedure which, in itself, usually proves to be much more cumbersome, if not apparently more wasteful, than the ones that are commonly used and yet condemned owing to lack of ability in the operator.

A great improvement could be had if the present methods of ore-dressing were handled in a businesslike and satisfactory manner; but it would be very foolish to say that some new procedure would not prove, in some cases, more desirable than the known methods. You, Mr. Editor, and I know, that there is too much of a general tendency on the part of persons advocating new schemes to want to throw all of the good, known, tried processes out of commission and immediately start off on new lines.

It is possibly several decades since the use of platinum sponge as a catalyzer for the union of sulphur dioxide and oxygen was first announced. It has taken all of these decades with much expensive and strenuous investigative work, coupled with high engineering ability, to evolve schemes which are now known as "contact processes" for the manufacture of sulphuric acid. Even at that, the contact processes will compete only under given commercial conditions. When, therefore, a person drops into the complex-ore field and immediately announces a new process, one is inclined to be skeptical as to the engineering of it, at least, although the fundamental principles involved may seem to be sound. It has been repeatedly proven that a simple procedure, coupled with high operative efficiency, usually beats any intricate procedure having too great a demand for high class labor and care in watching the various steps. The answer in any case is a matter of dollars and cents. If the old procedures, which may seem to be somewhat wasteful, cost little for operation and something more for actual loss of metal at its valuation at the point of treatment, and these costs prove to be less than those of some more elaborate procedure having possibilities for higher recoveries, it is merely a question of the survival of the fittest, which, in this case, will be the scheme first outlined. With the possible exception of electric zinc smelting as now being tried out, it has been proven under any conditions that I know of that complex ores should be treated by simple ore-dressing, followed by the old procedures, as against any new chemical or other sort of a scheme outlined to date.

3.—I do not think there are many mines now idle for lack of suitable treatment processes. I know of several "scouts" of the large companies who complain that they are unable to locate such large tonnages of ore as several enthusiastic people are inclined to believe exist.

4.—There are two conditions which might obtain: one is where the various constituents are so finely disseminated that extremely fine grinding is necessary; and the other where the mineral particles are composed of the metals upon which separation is desired. In other words, chemical combination or fine mechanical combination makes these ores refractory to present processes.

5.—Mechanical methods, coupled with the various smelting processes for the different metals, is the general procedure now adopted. The hydrometallurgical schemes do not seem to offer much for the reason that they necessitate the handling of salts of high heats of formation in large volumes of solution, calling for a high investment cost and demanding expensive chemicals. I think the electrometallurgical presents the only line worth while, in that either the electrothermic or electrolytic methods may be undertaken. With regard to the latter, one must be sure of the commercial aspect and first go thoroughly into the power situation. With the prospect before us of cheaper power from hydroelectric stations, some electrometallurgical procedure should be evolved which will ultimately yield cheaper metal. .

In passing, since there are fads in metallurgical lines as well as in others, I might note that we are going through a stage when the whole fraternity is on the qui vive trying to make every ore amenable to treatment by some flotation process. In the case of one-mineral separation in the United States this process has proven an aid; but it is of no benefit in the case of ores of zinc, which are truly complex, although being advocated for such. I do not know of any complex ore in Colorado, for instance, that could possibly show any advantage under this treatment.

6.—Almost every one examines ore with a magnifying glass or even goes so far as to use a microscope. We use both and are guided thereby. Almost every one in the ore-dressing business or ore-handling business uses on or the other and gains a great deal of information. When it is indicated by magnifying that extremely fine crushing is a necessity, mechanical separation then becomes out of the question, unless under peculiar circumstances.

Denver, Colo.

**Arthur J. Hoskin.**—1.—Yes, such a problem does not exist. To me a complex ore is one that contains or is made up of two or more base-metal minerals—not necessarily sulphides—each of which could be marketed if suitably separated or otherwise prepared to fit commercial demands. In some instances of ores containing more than two minerals, it may be sufficient to make but two products. Thus, if an ore contain galena, sphalerite and chalcocite, the three metals thus represented could each be realized upon in the market if the sphalerite were removed cleanly from the other two minerals. I once considered an ore composed principally of sphalerite and barite complex. I had such an ore and was assured of a good market among paint manufacturers for clean oxide of zinc and sulphate of barium. It was before the days of electrostatic, flotation and magnetic separations. The minerals of the ore could not be effectively separated by the then existing table methods, either wet or dry, as their specific gravities were nearly the same. To me it was complex, but both minerals were not sulphides. I would certainly call a mixture of molybdenite and biotite complex, since I understand that these minerals do not separate well under any of the present processes, and yet there is a market for each mineral when clean.

2.—Certain combinations of minerals that are now classed as complex ores are undoubtedly amenable to present methods in the hands of skilled operators; but there are other ores, the satisfactory dressing or treatment of which has not been discovered.

3.—I know of a few mines lying idle from this last cause, and I presume there are many.

4.—Among the physical properties that have thus far proved obstacles in the thorough separation of such minerals I would mention similarity in specific gravity; shapes of crystals; similar action in flotation; equivalent electrical properties; similar magnetic properties; equal solvency in chemicals; similar action under heat.

5.—It would seem that there is a field for all three general sorts of treatment.

6.—The microscope would reveal such peculiarities of the physical structures of the associated minerals as would be useful in deciding upon the degree of fineness to which ore should be ground, and it might also determine the most desirable method of pulverization.

Denver, Colo.

**George H. Scibird.**—I define a complex ore as a difficult ore, or one which is refractory to profitable treatment by ordinary prevailing processes; and with this definition in mind, the statement that there has existed a complex-ore problem, locally, becomes true. To convey some idea of the nature of one such ore, the following analysis is given:

| | |
|---|---|
| Gold | 0.11 oz. per ton |
| Silver | 11.00 " " " |
| Insoluble | 85.00 per cent. |
| Iron | 2.75 " " |
| Manganese | 2.25 " " |
| Lime | 3.00 " " |
| Copper | 0.60 " " |
| Lead | 1.00 " " |
| Zinc | 1.25 " " |

The character of this ore is such that concentration by any practicable method was unsuccessful, while only fair results were ever obtained by combination of various processes.

In this particular case, it is improbable that skill on the part of the operator would have helped the situation, because the metals existed in the ore in such a condition that their recovery apparently was impossible within commercial bounds. In this respect the ore was not amenable to treatment by existing, proved processes. Thus it became evident that either a new process must be found, or some old process, with modern methods applied, be revived. In fact, this has been done. In developing the process an effort was made to overcome the weaknesses of the old chloridizing-roasting process, such as loss by volatilization, high cost and low extraction, and by improved chemistry in the use of solvents. The application of modern, highly specialized machinery will also prove of great benefit in the new plan of treatment. Thus, the Christensen process, strictly speaking, is not new when considered as a revival of the chloridizing process, but it embodies new ideas in a very large measure, and is so improved that it bids fair to take a most important position in the treatment of what have been complex ores in the sense of my definition.

While there are not, locally at least, many mines that are actually idle for want of such a process, there are many which are seriously hampered by a vast tonnage of non-smelting-grade ore which may well become a valuable asset with the adoption of this treatment. When, however, the country at large is considered, there are several properties, now idle, which can readily be remembered, that could be made profitable by the new process, and there are more which might operate to better advantage with this method of treatment than under their present process.

There are several features which have proved detrimental in connection with the ore. First may be mentioned the value. This figure is such that smelting is out of the question. Secondly, the base metals occurring as carbonates and chlorides, with the gold in an extremely fine state of division, makes concentration unsatisfactory; while cyanidation either alone or in combination with concentration is only fairly successful. Leaching with various solvents, roasting, and in fact the whole category of usual procedures, is not promising. The new process, however, promises to save the situation.

Thus, at least locally, and to a considerable extent, generally, the modernized chloridizing-roasting and leaching process will prove of immense value in solving the difficulty, although where the gangue is limestone this process is not perfect. It will, however, make available the value in a tremendous tonnage of ore which is at present worthless.

Salt Lake City, Utah.

**R. D. George.**—My various trips to the San Juan and other districts in Colorado, particularly in Boulder county, have led me to the opinion that there are large quantities of low-grade ore in the State which cannot be profitably treated by the present methods. A great deal of money is spent on processes, plants, and mills of various kinds without scientific investigation of the material to be treated, and the adaptation of the methods to local conditions.

1.—I have heard the term "complex ore" applied in the following cases:

a. Where the metals contained in the ore are in minerals of like specific gravity and therefore difficult to concentrate. An example of the kind would be zinc sulphide and pyrite.

b. Where the metallic contents are so disseminated through the gangue material as to make concentration difficult, if not impossible. This is the case with some of the tungsten ores of the eastern part of the Nederland area where cherty quartz and ferberite are so intimately mixed in such small grains that any type of crushing leaves the ferberite grains with sufficient gangue attached to make a low grade concentrate, and the quartz grains carry away sufficient attached ferberite to make the percentage of saving low.

c. Where there is considerable variation from place to place in the quality of the metallic mineral contained, as in the San Juan region where the silver, for example, may occur in any one of ten different forms, such as native silver, argentite, cerargyrite, stephanite, pyrargyrite, freibergite, proustite, silver-bearing tetrahedrite, silver-bearing tennantite, and argentiferous galena, along with pyrite, chalcopyrite, sphalerite, anglesite, hinsdalite, and a dozen others, and gangue minerals such as rhodochrosite, rhodonite, jasperoid, etc.

d. Ore deposits in which no definite line can be drawn between the oxidized and the unoxidized portions and in which sulphides, carbonates, oxides, and tellurides are intimately mixed.

e. To deposits in which many metallic bases of value are mingled in the same ore, as in some places in the San Juan region where operators are puzzled to know whether their values are chiefly in the form of lead, silver, gold, copper (tungsten), or zinc, or all of these together.

2.—I believe that modifications of present processes to meet local needs could be made by experienced and skillful operators in such a way as to overcome many of the difficulties. Again cooperation between treatment plants would make it possible for specialization in mills to meet the demands of certain types of ores. In the past, the custom in building mills has been to generalize in such a way as to meet every possible type of ore. This seems to me to be contrary to scientific principles and economic considerations.

3.—I am more familiar with conditions in Boulder county than with those in most other parts of the State, and I am convinced that, with suitable concentration plants and other treatment processes, idle mines of Boulder county could furnish a very large tonnage. This is also true of parts of Gilpin and Clear Creek counties, particularly the Georgetown and Silver Plume areas.

4.—This question has been answered rather completely under No. 1.

5.—I believe that the varieties of ore and the purposes for which they are treated are such as to demand mechanical improvements in concentration, modifications of the hydrometallurgical processes, and to warrant more thorough and careful electrometallurgical experiments.

6.—I have long advocated the careful microscopic examination of the so-called complex ores as an aid to the mill man and the metallurgist. I talked this matter over with Dr. Holmes of the United States Bureau of Mines some years ago, and urged the desirability of attacking the problem from this standpoint. I also outlined a method of attack, and the data to be sought in such methods. I believe that some work has been done since by the Bureau of Mines, though I do not know the extent of the work or its results.

Boulder, Colo.

**S. E. Bretherton.**—Yes, there is a complex-ore problem. One type of complex ore is a sulphide containing both zinc and copper, zinc and lead, or zinc, copper and lead, with or without silver and gold. I might name another complex ore, low-grade, silicious, oxidized copper ore. The absence of sulphur and high percentage of silica prohibits such ore being smelted for the production of copper matte, if such ore is located in districts where iron sulphides are not plentiful. Concentration of such oxidized copper ore is not practical, and the presence of alumina, iron and often some lime makes leaching methods by the use of acid too expensive, even if cheap metallic iron should be available for the precipitation of the copper after it is obtained in solution. The leaching of either copper or zinc ores when oxidized, often called carbonates, is not generally suitable for the ammonia carbon-dioxid process, as such oxidized ores are usually mixed with considerable quantities of silicates of copper or zinc, which prevents a high extraction by this last named process. For this reason I am more particularly interested in the treatment of sulphide ores, from which, after an oxidizing roast, the zinc can be recovered by leaching with ammonia and carbon-dioxid, and the other valuable metals recovered by the usual methods of smelting.

2.—When the ore is a sulphide and of suitable crystalline structure, zinc and lead can generally be separated by some of the ordinary methods of concentration, and sometimes zinc and copper can also be separated, but usually with excessive loss of gold and silver when the ore is rich in precious metals; but in a great many cases the structure of the ore will not permit of this mechanical separation. I believe there is a need for new treatment processes.

3.—Yes, if zinc could be added to the value of the ore in addition to the other metals, instead of being deducted by being penalized when the other metals are sold to the smelters as at present.

4.—Zinc is difficult to separate from copper by concentration. If the ore is smelted direct, the cost to recover the copper is increased by the presence of zinc, and the presence of zinc is much more objectionable when smelting an ore for the recovery of lead. (See answer to Question No. 1.)

5.—The processes most suitable would depend very much on the location of the mine where the ore is to be treated, as well as the analysis and structure of the ore. In some cases for sulphide ores, all three of the processes named may be required. Electric smelting with very cheap water power may come to the assistance of the retort or fire process, but even then considerable fuel is needed as a reducing agent with the roasted zinc ore, and a very expensive plant installation. For this reason it is reasonable to expect more development for the treatment of complex sulphide ores along the lines of concentration and leaching, and leaching direct. The complex zinc and copper sulphide ores of California are different in their structure to ores of the same analysis in Colorado, Utah and Arizona, and no known method of mechanical concentration is suitable for the ores of Shasta Co., Cal. Containing, as they do, considerable alumina and lime, any acid process does not seem suitable. For this reason the writer has developed the ammonia carbon-dioxid leaching process, which, so far, seems the only suitable process, requiring no fuel excepting oil which is the cheapest fuel in California.

6.—I would consider microscopical examination of any complex sulphide ore of material assistance in suggesting proper methods of treatment, as no doubt by experience the metallurgical engineer could decide in a short time whether mechanical concentration was suitable for the ore to be treated or not. We find that a powerful magnifying glass is a great assistance to us to quickly decide when the ore is properly roasted, and a more convenient and quicker means for the man in charge of the roaster than is the ordinary laboratory test.

San Francisco, Cal.

**William G. Haldane.**—1.—I think there is a "complex ore problem," although the term is used rather indiscriminately. I apply the name "complex ore" to such as exists in the San Juan region of this state, finely disseminated and intimate mechanical mixtures of the sulphides of copper, iron, lead, and zinc, and others of a similar nature.

2.—I believe that present processes in combination in the hands of skilled operators would accomplish much towards the solution of these problems, due to improvements and developments in the processes themselves, resulting from experimentation and use by such operators.

3.—There is not "millions of tons" of such ore, but an attractive field would be opened up if new processes were developed.

4.—The difficulties encountered in processes at present are largely mechanical, and result also from the

See "Preparation of ore containing zinc for the recovery of other metals, such as silver, gold, copper and lead, by the elimination and subsequent recovery of the zinc as a chemically pure zinc product," page 1141 in the August, 1913, *Bulletin of the American Institute of Mining Engineers* and F. L. Wilson's article on the same subject in the *Mining & Scientific Press* of March 14th last, page 453 attempt to use the same medicine for a number of widely different ills.

5 and 6. Am greatly in favor of combination methods. I think the tendency has been to apply to an ore containing a number of minerals, each with its own special characteristics, a process involving only one principle, as, for example, specific gravity. To illustrate further, an ore may contain, let us say, minerals 1, 2, 3 and 4, with 1 and 2 of high sp. gr. and 3 and 4 of low sp. gr. In this case a preliminary concentration and separation may be effected with tables. Minerals 1 and 2 may be widely different magnetically, or may be readily separated with electrostatic machines, and so on.

I thoroughly believe a microscopic examination would be of very great assistance as a preliminary step in the examination of these complex ores. It reveals properties and information at first hand that should be invaluable to an investigator. The microscope should be one of the first pieces of apparatus resorted to by every technical man in the investigation of the characteristics and physical features of an ore.

I am firmly of the opinion that our problem is a metallurgical one, but I believe closer attention to details and manipulation of our present processes will result in higher efficiencies and greater economies.

Golden, Colo.

**Warren F. Bleecker.**—1.—The term "complex ore' is an unfortunate one, because it does not mean anything specifically, but may be applied to any ore containing two or more valuable metals. In certain Colorado mining districts when one speaks of a complex ore he refers especially to base-metal sulphides containing zinc. In this sense the term is more or less reflective, since the method of treatment is the thing which is really complex. Unless one had the authority to limit the meaning of this term, he certainly could not embrace all of the meanings in a definition of unlimited length. For example, the mineralogist might place three vanadium minerals in the following order of complexity: roscoelite, carnotite, patronite. The technologist would certainly reverse the order. And I have reason to think that the analytical chemist would establish still another order of complexity for these three common vanadium-bearing minerals.

It is apparent, however, that the question refers to the base-metal sulphides. Those of the base-metal sulphides may be called complex which cannot be treated by standard mechanical devices; or in which no one valuable metal is in sufficient quantity to warrant profitable treatment; or in which there is a small quantity of zinc or a larger quantity of zinc which is chemically combined with the other values. It is obvious that if there were some cheap chemical which could be applied to cause the metals to be quickly and cheaply separated, the term complex would cease to be applied.

2.—Each ore presents a separate problem, be it a complex ore or a placer dirt, and the only method of getting at the truth will be the examination and report made by a reliable laboratory; or, still better, to send several carloads to a mill operating on a similar ore. If the mine is not exhausted by the loss of this quantity of ore, and the milling process is even moderately successful, the proposition would be very hopeful.

3.—I do not believe that there is a large quantity of good ore now developed and awaiting suitable methods of treatment. At the same time the present methods of ore-treatment are deficient, and development is held back accordingly. As known methods are improved and new ones devised, there will still be ores which are just on the line, and which will make further demands on the technologist.

4.—The quality of complex ores which contributes chiefly to their refractoriness to present processes is the distribution of values among several elements. Each element requires different methods of procedure in its extraction and subsequent recovery, and often it will cost more to recover an element than it is worth. For example, zinc is very troublesome, especially when chemically combined with iron. If the gold and silver also are with the iron, considerable difficulty will be experienced in getting any of these products out in a marketable form.

Another quality, which is a negative one, is a distinct lack of values in the ore to begin with. An ore is not necessarily worth treating because the total values foot up to ten or twenty dollars per ton. The aluminium from a clay carrying twenty per cent alumina would have a market value of fifty dollars, yet some difficulty would be encountered in deriving a profit from the treatment of such an ore. A true roscoelite carrying five per cent vanadium pentoxide might be said to have a value of $120 per ton, on the basis of a finished ferrovanadium, yet it would cost more than this to extract all of the vanadium and produce a marketable product from this class of ore.

5.—The problem is so indefinite, if indeed any problem exists, that it cannot be predicted which method of treatment will finally solve it. A shrewd guesser might do well to say electrometallurgical, because when taken in its broadest sense this term includes the other two.

6.—A microscopical examination would reveal the extent of mineralization, the size of crystals, and the general relation of the component parts of the ore. It is of great value to know what elements of the ore carry the values, and what its general physical conditions are.

I am of the opinion that complex ores which occur in sufficient quantities have a reasonably high metallic content, and show a fair paper profit after deducting standard costs and charges with a recovery of 50 or 60 per cent, will not have to wait long for a suitable method of treatment.

Canonsburg, Pa.

**S. A. Ionides.**—1.—The best answer I can give to the question "Is there a complex-ore problem?" is to quote from a letter recently received regarding an ore assaying about 5 oz. silver per ton, 14.5 per cent lead, 13 per cent zinc and 0.25 per cent copper.

> "I note our recent shipments of ore are running exceedingly high in zinc, frequently reaching 17 per cent. The lead content remains normal, but we are having the life penalized out of us because of the increase in zinc."

As long as a valuable metal is a source of penalty, instead of being an asset, there can be no doubt about the existence of a complex-ore problem.

Another phase of the problem is the loss in slime-tailing. Two such problems have recently reached me. In one case the slime tailing assayed 4 per cent lead, 2 per cent zinc and 2 oz. silver per ton. It constituted 20 per cent of the original feed to a concentrating mill which is regarded as doing excellent work.

Another slime tailing from a mill where the work is not so high class contained 17 per cent lead and 11 per cent zinc. Undoubtedly a lower tailing could be obtained from the latter mill by straight concentration, followed perhaps by flotation, but even so, the product would have a low economic value.

A complex ore may be defined as ore containing two or more base metals. In its simplest form such an ore need not give trouble. For example, a copper-lead ore containing precious metals is easily treated. A more limited meaning frequently is implied by the term "complex."

It involves the presence of zinc in the ore; and no instance is known to me where high recoveries of all metals are made from an ore containing lead and zinc, copper and zinc, or all three.

2.—Such ores as the one just mentioned have not proved amenable to treatment by present processes, in the sense that extractions exceeding 90 per cent of all metals can be made. It might almost be safe to say that this standard is never reached, for even if concentration was efficient, the smelting losses would reduce the total recovery below that figure. That there is a need for new treatment processes is evidenced by the fact that some of the large companies handling comparatively simple ore, are now engaged in elaborate experiments on new methods, particular reference being made to the copper leaching plant at Anaconda.

3.—From the number of inquiries received for methods of treating complex ores, there can be little doubt that a number of large mines require improved metallurgical processes. If the low-grade (10 per cent to 20 per cent) zinc carbonate ores of Leadville are admitted into the complex class, an estimate of "millions of tons" would be safe.

4.—The element that contributes most to the refractoriness of ores is zinc, and the quality or characteristic is friability.

A good commercial product can be made from ores containing copper or lead with precious metals; but inasmuch as a recovery of over 80 per cent is rarely made in practice, it may almost be said that these ores are refractory. The loss, in most cases, is due to slime; and the slime product from a lead or copper ore certainly is refractory.

The problem of concentration of coarse grades has practically been solved, and there is not much opportunity left for increasing the saving or reducing the cost.

Even so, there is room for improvement; for the miner still has to stand smelting and refining as well as concentrating losses.

The presence of zinc in an ore gives trouble all the way down the line, and if recovered with the lead it becomes a liability and not an asset. This point is accentuated as attention is now being directed largely to the solution of this particular problem.

5.—A solution of the problem along purely mechanical lines seems doubtful. Slime that will pass 150-mesh screen is invariably made in grinding, and the amount thus made frequently amounts to 20 per cent of the mill feed. The metal contents of this slime—gold, silver, copper, lead or zinc—usually will equal, if not exceed, that of the original ore. The only way this slime is being handled at present is by flotation, and while this process does efficient work where only one mineral is involved, it will not separate two. At best, one may be recovered; the other lost.

This year much work is being done along hydrometallurgical lines, but at the time of writing no method has been demonstrated a complete success. The most hopeful methods involve leaching with sulphuric acid, for copper ores, and a chlorination treatment for lead and zinc.

The electric furnace has proved its value in refining steel, making alloys, aluminium, etc., and there would seem to be a good field for it in ore treatment. This may be the method of the future, but at present it has not advanced as far as hydrometallurgical methods, combined, if necessary, with electrolysis as a final step.

Denver, Colo.

## Program of Troy Meeting, American Institute of Chemical Engineers

The sixth semi-annual meeting of the American Institute of Chemical Engineers will be held at Troy, N. Y., from Wednesday to Saturday, June 17 to 20, 1914. The technical sessions will be held at the Pittsburgh Building of the Rensselaer Polytechnic Institute and at the Hotel Rensselaer, the latter being the hotel headquarters.

There will be technical sessions on the morning and evening of Wednesday and on the morning and evening of Friday. The following papers will be presented on Wednesday morning:

The Application of Physical Chemistry to Industrial Processes. By W. F. Rittman.

Studies on Filtration. By J. W. Bain and A. E. Wigle.

Scrubber for Vacuum Apparatus for Laboratories. By Chas. Baskerville.

On Wednesday night, Professor M. C. Whitaker will present his presidential address. This will be followed by an illustrated lecture by Dr. Wm. P. Mason on the Saratoga Septic Tanks.

On Friday morning the following papers will be presented:

Shoddy and Carbonized Waste. By L. J. Matos.

The Present Patent Situation. By M. Toch.

Bleaching Cotton Fibre. By J. C. Hebden.

Ozone in Ventilation. By J. C. Olsen and Wm. H. Ulrich.

The program for the Friday night session comprises the following two papers:

Development of Rotary Furnaces. By R. K. Meade.

A Combination Water Softener and Storage Tank. By L. M. Booth.

A great many visits and excursions are scheduled for Wednesday afternoon, the whole of Thursday, Friday afternoon, and the whole of Saturday.

On Wednesday afternoon the laboratories of the Rensselaer Polytechnic Institute and the U. S. Arsenal, where heavy guns are manufactured, will be inspected.

On Thursday morning the General Electric Co. plant at Schenectady will be visited and in the afternoon the filter plant at Albany, besides an automobile trip to Saratoga.

On Friday afternoon an excursion will be made to the plant of the West Virginia Pulp and Paper Company at Mechanicsville. On Saturday morning the Burden Iron Works will be visited where the puddling process for wrought iron will be shown. For the afternoon visits to the Cohoes filter plant (mechanical filters) and to the plant of the Freihoffer Baking Company are scheduled.

Among the social features of the Convention will be a subscription dinner at the Troy Club on Thursday night, a smoker at the residence of Dr. Mason on Friday night, and complimentary luncheons tendered by the Rensselaer Polytechnic Institute on Wednesday noon and by the General Electric Company on Thursday noon.

Professor M. C. Whitaker is President and Dr. John C. Olsen, Polytechnic Institute, Brooklyn, N. Y., is the Secretary of the Institute.

---

Two chloridizing plants are expected to be in operation this month. The first is that of the Northwestern Metals Co., at Helena, Mont., where experimental work has been going on for several years. The other is the Knight-Christensen mill at Silver City, Utah. The details of the process used differ, but the underlying principle is the use of chlorine to render soluble the base and precious metals.

# Light from Unconsumed Electrodes

BY A. VOSMAER, PH.D.

The nature of the discharge which takes place between the electrodes of the arrangement that I shall describe presently has been puzzling every one who has watched it when demonstrated in my experimental laboratory in Holland. The discharge, causing an intense light, is absolutely steady, does not resemble any other, and does not cause any permanent change in the electrodes. In other words, one can obtain a light without consuming the electrodes, which seems something promising in the art of lighting. The discharge itself is not visible, which may be on account of the intense light at the electrodes. Occasionally one is able to distinguish a pale bluish-violet streak—straight, thin, tiny and faint—between the electrodes, but that does not seem to be the essential discharge which produces the effect of light.

The literature on discharges *in pleno* is not very elaborate. Lehmann, Toepler and Warburg have dealt with them at some length, and Lehmann especially has given full information about the subject, but the discharge I shall consider presently does not fall in the class of any of the many discharges mentioned by these investigators. Let us first review the five fundamental discharges *in pleno*, and consider the diagrams given by Toepler[1] in discussing the question of boundary potential differences for different kinds of discharges. Toepler, using a sixty-plate influence machine, distinguishes sharply between the discharge from the positive and that from the negative electrode, and the graphs, Figs. 1 and 2, clearly show the difference in effect. We see a discontinuous line, indicating boundaries between the different discharges; first the non-visible, then the glow, the brush, the spark and the arc.

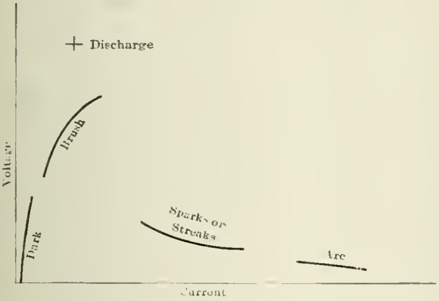

FIG. 1—DIAGRAM OF DISCHARGE

In alternating high-tension discharges, the current being supplied from a transformer, we must place the flame discharge between the spark and the arc. A static machine cannot give flame or arc discharges as transformers do, the current supply being inadequate and the working proper of the static machine ceasing when its electrodes are short-circuited, so to speak, by an arc discharge. The static machine is essentially a high-tension machine; but the flame and arc are essentially low-tension discharges. Consequently this machine is not adapted for the production of such discharges, but for the study of glow, brush and spark discharges it is better adapted than any other.

Toepler observed that in the actual production of the discharges there are no such things as definite boundaries, and he joined the lines by shaded parts. Fortunately he did not give different names to every part. In 1908 Cramp and Hoyle took up the matter again and confirmed Toepler's results. These investigators gave very interesting graphs for the relation of voltage to amperage, of which Figs. 3 and 4 are reproductions. They refer to the low-tension side and to the high-tension side of the transformer, and are an amplification of Toepler's lines.

If we consider the glow to be the beginning of *overcharge*, and hence *discharge*, and the brush the period of regular gentle flow of electricity (from points), and the spark as the result of accumulated charge (from spheres), then the flame and the arc distinguish themselves from these in that they are low-tension phenomena, the others being high-tension discharges. If we take the flame discharge as being due principally to the conductivity of the gas at high temperature, then the arc may be considered as the controlled discharge due to transport of solid matter between electrodes. None of these ways of considering the discharges is correct, but they are given thus for the sake of reference.

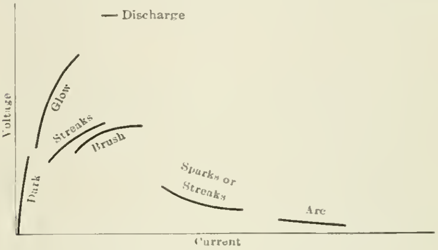

FIG. 2—DIAGRAM OF DISCHARGE

Now the particular discharge under consideration could be called a high-tension arc discharge, because the potential difference between the electrodes is about 500 volts, as against about 35 to 50 for the ordinary arc; but since the arc light is accompanied by transport of solid matter, there is a difference between it and the light under consideration, in which nothing of the kind occurs. Neither is it a flame, a spark, nor a brush. The ill-defined discharge sometimes called "streak" is the only one most nearly resembling it. The peculiar features of the discharge in question are its high tension, viz., about 500 volts; its steadiness; the absence of electrode matter in the flame; the extreme temperature; its sensitiveness to polarity, as well as to frequency when alternating current is being used.

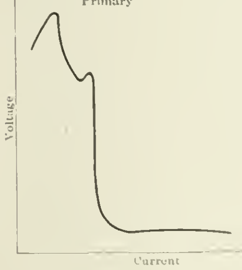

FIG. 3—VOLT-AMPERE CURVE

What is it? That is the question asked many a time, but as yet unanswered. Therefore, it may interest the reader to hear more about it. The production of this very peculiar discharge is simple indeed for those who are accustomed to making experiments, and who have that inborn sense of adjustment of conditions that distinguishes the true experimenter from the haphazard investigator.

---

[1] Ann. d. Phys. 1902, 7, 477.

As the question of polarity plays an interesting rôle in the phenomenon, it is best to take a good-sized Rhumkorff induction coil, preferably equipped with a modern Wagner hammer, allowing of close regulation. We might remind the reader that the induction coil fed by an interrupted primary current will give an alternating secondary electromotive force, due to the difference between the make and the break; but it should also be remembered that the value of said secondary tension depends, for one thing on the *rate* of appearance and disappearance of the lines of force. Now the great self-induction of the coil prevents a rapid "make," but the "break" can be very rapid, indeed, if proper means are provided. A condenser of right size is very important.

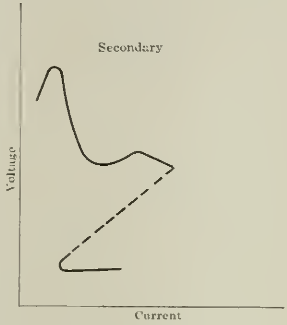

FIG. 4—VOLT-AMPERE CURVE

The great difference in time required for the make and the break, taken electrically, of course, causes a very marked difference in the magnitude of the secondary tension, so marked indeed that we may consider the secondary output to be practically an unidirectional, though intermittent, current.[2]

In Fig. 5 we give a representation of these considerations; the actual rotary mirror photographs look a bit different, but this diagram is true in principle.

As we shall refer to this point again, it may be well to say here that as the difference in polarity of the secondary terminals of a Rhumkoff coil is caused by the great difference in the time of appearance and of disappearance for the magnetic lines of force, the difference can be changed by variation in interruption, as regards speed of working, etc.

Suppose we have this induction coil as we want it, then all we have to do is to join the secondary terminals to an adjustable spark-gap allowing of rapid adjustment of polar distance of electrodes. Now take two bits of pure nickel wire, fix these in said electrodes, and all that remains to be done is to so regulate the different factors that the effect is obtained. The polar distance between the ends of the two nickel wires should be about 2 millimeters to start with. On setting the vibrator to work the ends will burn and form globules. Now adjust (while working) the polar distance until it is about 3 or 4 mm., and when once formed the discharge will go on for any length of time without further adjustment of electrodes. This is one proof that they are not consumed, for if they were the polar distance would be increased and there would not be a permanent condition.

As it is, no such thing as burning occurs. The discharge, when once properly established remains absolutely steady and can be watched and admired. We used to observe it in the cross wires of a telescope and never noticed change of place.

A more stringent proof of non-combustion is that in the spectroscope nothing but a pure continuous spectrum is to be seen, such as belongs to incandescent solid matter. No trace of lines is observed. If there were any transport of nickel, the vapor would show in the spectrum. Now some experimenting has to be done in order to get the right size of wire, corresponding to the size of the coil. My coil was a 12-inch, or a 4-inch spark length; the nickel wires were about 1 mm. for the first and 0.6 mm. for the second.

The explanation of the phenomenon is not easy to give. Probably the surface tension of molten nickel oxide happens to be so great that it maintains a certain volume, and the bombardment of electrons causes it to be white hot.

If, instead of nickel wire we take platinum, the latter will melt rapidly. In fact I have been able to melt or sinter almost anything in this little crater. Such substances as lime or quartz melt easily, but some of the rare earths only sinter.

The mistake of considering a flow of electricity to go from plus to minus is so common that we no longer pay attention to it, everybody knowing it to be the reverse. The best illustration is given by an ordinary carbon arc, wherein the positive, hollowing out to a crater, cannot very well be regarded as emitting particles. It was Armstrong who, in his beautifully illustrated work, "Electric Movement in Air and in Water," showed that current conduction is accompanied by mechanical movement of the conductor, if possible, and in the direction of negative to positive. So we are used to considering the negative electrode as the active, or discharging one, and the positive as the receiving department.

I have more than once drawn attention to the fact that in case we are dealing with true brush discharges it is *not* the negative but the positive electrode that discharges. Warburg holds the opposite view, but Toepler, Przibram, Cramp and Hoyle do not. In the present case, again, it is not the positive electrode that emits the light, but the negative; the positive being quite dark.

This anomaly may be emphasized. The case we first consider is that the electrodes are of the same material and the same size. If the sizes are unlike, say the negative a thin wire and the positive a thicker one, then we do not reverse the light emission but simply have a poor effect.

The effect, as stated, is shown best of all by pure nickel; next come some of the nickel alloys; but other metals do not exhibit the phenomenon in the proper way.

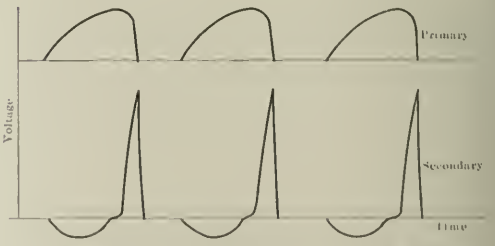

FIG. 5—PRIMARY AND SECONDARY VOLTAGE CURVES

When we feed the induction coil with alternating current or take an ordinary transformer, the effect is that instead of only one of the nickel electrodes glowing, both nickel electrodes will be glowing, as might be expected. But when we now substitute a copper wire for one of the nickel wires the result is that one, viz., the nickel electrode, glows, while the other, the copper electrode, is absolutely dark.

Remembering now what was said about the character of the induction coil's secondary current, we can make another interesting experiment. Upon slowing down the speed of the vibrator (and it is just for this purpose that a hammer interrupter was preferred over any of the more modern kinds) the difference in the rate of appearance and disappearance of lines of force will also fade away, and there comes a moment when the unidirectional character of the secondary tension is lost altogether. At that moment, or period of transition, both of the nickel ends will light up, and on further slowing down it will be possible to have only one of them glow again, but not the same one as in the beginning.

---

[2] Polarity of terminal is easily ascertained by having a strip of moist litmus paper on a strip of glass and holding this between the terminals, the plus shows in red as sharply as the minus in blue.

We must leave it undiscussed whether or not this is due to a change in preference for the negative electrode to glow or to some other reason. The question is very complicated and instead of adding to the elucidation of the difficult problems in discharges it only adds more mystery. As to the commercial side of this phenomenon, it must be remarked that at present the experiments have been made on a very very small scale. Primarily it is a matter of scientific interest; but if we consider the possible value of a light from unconsumed electrodes, whereby all the trouble and expense of trimming is done away with, it seems worth while to investigate the matter on a larger scale and I hope to be able to do so when opportunity offers. For the present, the object of publication is only to communicate a remarkable and unusual discharge phenomenon.

341 St. John's Place, Brooklyn, N. Y.

## Factors Affecting the Cost of Copper

In the annual report of Phelps, Dodge & Company for 1913, Dr. James Douglas, president, makes the following pertinent remarks relative to the company's operations in Arizona, New Mexico and Mexico:

"Judging from the average stability of price during a period of years we may infer that the price of copper in the future will not be lower than realized during the expiring decade. In fact, the price of the future should be higher to compensate for the increase in expense of producing the metal.

"Under legislative enactment and social aspirations the demands of labor will be more exacting, and the taxes, representing the cost of government (municipal, state and federal), will become more onerous. The mines, being always under corporate management, will have to bear more than their share of the burden. The state taxes paid by this company and its subsidiaries have risen from $431,559.76 in 1912, to $605,431.78 in 1913, and federal taxes, amounting to $178,872.84 based on 1913 business, have been levied. The cost of concentrating and smelting can probably be lowered by improvements in both methods and practice, but, with greater depth and the general decline in the grade of ore, the cost of mining will tend upwards rather than downwards; and the inevitable exhaustion of the company's mines must be anticipated and provided for by acquiring additional mining property. With this in view the mines of the Burro Mountain and the Chemung Company in New Mexico have been bought, and additions have been made to the property of the Detroit Copper Company, whose visible reserves have distinctly fallen off. This, fortunately, has not been the case in the Copper Queen and the Moctezuma Copper Company's mines, where the increased activity has resulted in largely increased tonnage of ore in sight."

---

The **P. Wall Mfg. Supply Company**, of 718 Preble Avenue, N. S., Pittsburgh, Pa., has sent us their new, well illustrated catalog on "Wall's Everlasting Steel Specialties," especially brazed steel oilers and torches, steel gong bells, galvanized steel ice cans, sheet metal specialties, copper-plated oilers and torches, etc.

## Tropenas Converters vs. Electric Furnaces for the Manufacture of Steel Castings

By G. Muntz

No one will begrudge the Tropenas converter the honor of having been among the early pioneers who made the steel casting business one of the most important in the world. Steel men are too broad minded to forget those who had the courage of their convictions and made it possible to obtain to-day a product which has become a decided factor in the manufacturing community.

It seems, however, that the fact has been overlooked that although steel as found in channels, I-beams, rails, etc., has almost the same characteristics as the steel that goes to make steel castings, the peculiar conditions inherent to the two manufactures are absolutely different.

We all know what the Tropenas converter can do and it is only necessary to state the claims of the electric furnace used to-day to manufacture steel castings:

1. The metal obtained is lower in phosphorus and sulphur contents than converter steel.
2. Segregation in electric steel is less than in converter steel.
3. Starting with cold steel scrap electric steel is cheaper to produce than converter steel.
4. Absolute uniformity.

We shall not take these claims and criticise them one after the other. We will simply draw a parallel between the Tropenas and the electric process and point out the obvious conclusions as we go.

### RELIABILITY OF THE TROPENAS PROCESS

It is well to define here what we call the Tropenas process. Side blowing is an old idea, and even Bessemer, in his converter at St. Pancras, was blowing through the metal on the side and near the bottom. Adamson, Clapp, Griffith, Witherow, Walrand, Robert, all blew on the side of their converters, but each farther from the bottom. We believe that Tropenas was the first to blow on the surface of the metal or better between the slag and the metal. This principle we think characterises the Tropenas process.

This point being now clear, we want to emphasize the extreme reliability of the Tropenas converter, even when operated by a seemingly inexperienced steel man.

We all know that the Bessemer process and its derivatives alike are first of all ideal means of decarburizing pig iron. A converter cannot be better compared than to an oil lamp. As long as the oil is plentiful, the lamp is burning brightly; when the oil gets low, the flame begins to flicker, and when the oil is almost gone the flame drops. In the converter we burn mainly carbon, a flame ensues which will flicker when the fuel is almost gone and will drop when carbon exists only as traces in the final bath. With a converter the signs indicating the end of the operation are absolutely unmistakable and the blowing itself is so simple that operators can be trained to be most reliable in a very short time. Steel making, by the converter process, depends mainly on good cupola practice whereby suitable metal is secured for refining in the converter. This feature is a decided advantage and must be taken into careful consideration when comparing the Tropenas process to any other.

The electric process, like the open hearth and other similar methods, entails the use of closed furnaces, in which no outward signs are in evidence when the steel has reached the suitable composition. Test bars must be secured at various intervals and the quality of the steel determined in various ways or by direct examination of the fracture.

It is easy to see that the personal equation plays here an important part, and that very experienced men must be secured to properly melt and refine in an electric furnace.

### THE ELECTRIC FURNACE AS A MELTING APPARATUS

Expert melters are scarce and command good salaries. Inasmuch as the electric furnace cannot compete with the basic open-hearth process, as far as cost of production is concerned, and is therefore limited to the small capacities, the resulting business ventures are comparatively small and do not admit of paying the large salaries which the big steel companies can allow to their experts. This is why the electric furnace has adopted the method followed by the old crucible process, whereby the furnace is used as a melting apparatus pure and simple.

The electric furnace has over the converter one great advantage, it can use such material as boiler punchings, turnings, borings, etc., which could not be melted in a cupola, meaning that although it is not as efficient a melting furnace as the cupola it can use cheaper raw material and thereby offset the loss in efficiency to its advantage.

In entering this field, the electric furnace, however, seems to violate the ever-present law of supply and demand. The recent stagnation of the steel scrap market caused such a great difference in prices between steel scrap and pig iron, that temptation might overcome better judgment resulting in the use of more electric furnaces, and consequently increased demand of such steel scrap as cannot be used in the converter process. Statistics show that although steel scrap is to-day at the same level as it was ten years ago, it has fluctuated very widely and often reached such levels as would have rendered the electric furnace a prohibitive melting method.

When determining the cost of liquid metal we find that the factors to be considered are well defined in the converter process, while in the electric furnace the main item, namely, the electric power is a very uncertain quantity. We will disregard the actual amount of current needed to melt 1 ton of steel, as opinions and experiences differ on that score, but there must be considered the cost per unit of the current itself. Steel foundries have given up the idea of manufacturing their own power. The investment required is too great compared to the returns to be expected, and the service offered by the electric companies is so superior that in most cases it is adopted. This advantage is offset by the fact that current is sold according to a sliding scale whereby rates decrease as consumption increases. It is found that in most cases the operation of an electric furnace is prohibitive when the number of operations does not allow the purchase of current at the favorable rates of the scale.

In other words, while a converter can be operated only once without great increase in cost of production, the same cannot be done with the electric furnace except at great loss.

This fact is worthy of consideration especially when one recalls the curtailed outputs which have prevailed for quite some time in the steel casting business.

### UNIFORMITY OF PRODUCT

It is a well-known fact that while melting in an electric furnace the phosphorus and sulphur contents will not increase, but so far as steel castings are concerned these two elements are not of such capital importance. This, however, cannot be said of the carbon contents of electric steel which are not controlled as easily as in the Tropenas converter. In the converter, with operations stopped always at the proper time, absolute uniformity is realized and steels of any carbon contents can be obtained at will by the use of suitable additions. Table I of fifty consecutive blows in two Tropenas baby converters shows what can be expected from the pneumatic process.

In the electric furnace, final additions of ferro-manganese and ferro silicon are made to either obviate oxidation of the metal or to carburize the steel to such an extent as will render it better suitable for the purpose intended, or both. The final product will then contain more carbon than the raw material first used, and inasmuch as at least 35 per cent of the steel poured is returned to the furnace in the shape of gates and risers, the carbon contents will keep on increasing, if delicate refining is not resorted to. However, if the percentage of risers and gates remains about constant, the carbon contents will decrease but only by decreasing increments and will never go over a certain limit.

The obvious conclusion is that the electric furnace as a melter will entail variations in carbon, which will occasion very noticeable changes in the physical properties of the steel produced.

TABLE I—TESTS FROM TWO TROPENAS BABY CONVERTERS BLOWING ALTERNATELY

| 11488 | 26 | .048 | 042 | .192 | 11530 | .26 | 056 | 049 | .226 |

Average manganese .80 to .90%. Variations in analysis are due to different weights of metal blown without altering weights of final additions. Average weight of blow, about one ton; average time of blow, 12 minutes.

Tests made by Michigan Steel Casting Company of Detroit, Michigan.

### CAPACITIES OF FURNACES

Most of the steel foundries to-day are jobbing foundries and are called upon to produce a great variety of castings, some of which are bulky but made of thin sections, others bulky and heavy, others again small and weighing only a few ounces. To meet the peculiar exigencies of the steel casting business a furnace must, therefore, be flexible and able to produce metal of such temperature and in such quantities as will be suitable for any class of castings. Proper temperature can be obtained in both the electric furnace and the Tropenas converter and either process can produce castings which could not be poured successfully otherwise. Very hot metal can be had at no additional cost in the converter at slight additional cost in the electric furnace. The whole problem reduces itself to one of furnace capacity.

The electric furnace has the advantage over the converter to allow control of the temperature of the metal. This feature is valuable when metal has to be kept in the furnace for some reason or other; once the correct temperature is reached, it can be maintained at slight additional expense.

Metal can be held in the converter but not indefinitely as in the electric furnace. This brings out the fact that the electric furnace is limited in capacity to its own charge. In other words, a 2-ton electric furnace will produce 2 tons of steel every two and one-half or three hours.

If we compare this to what can be done in a converter of equal charge capacity we find that from two to three operations can be made per hour, thereby allowing the accumulation of from 4 tons to 6 tons of steel per hour. We recall the instance of an 18,000-lb. casting being poured successfully with a single 2-ton converter. Six blows were made to secure sufficient metal, each blow being poured on top of the other in a ladle; it took one hour and forty-five minutes to make the steel and after the casting was poured there was not even a skull left in the ladle. This shows that even after waiting almost two hours the steel was still very hot.

This feature of rapidity of operation is one of the great factors in favor of the converter. It reduces itself to the fact that even should an electric furnace be as cheap of installation as a converter of equal charge capacity (which is not the case) it would take five or six 2-ton electric furnaces to produce the work of one 2-ton converter.

### SEGREGATION

The various impurities which are found in steel have different freezing points, and show a tendency to segregate and concentrate in certain portions of large bodies of cooling metal.

This segregation is affected by various factors such as initial temperature of the molten mass and especially the rate of cooling. From experiments made by Talbot in 1905 it was concluded that sulphur segregates most, phosphorus next, then carbon, and finally manganese. It was found also that the usual additions of aluminium reduced the segregation considerably.

Authorities differ as to the elements which segregate first, and Professor Howe shows that carbon segregates the most readily.

It is therefore interesting to apply either results to the particular case on hand.

The field covered to-day by the Tropenas converter and the electric furnace is such that metal manufactured by either process freezes almost instantly after being poured. Small and medium steel castings offer numerous surfaces of cooling and even if the steel produced by the converter process contains more sulphur and phosphorus than electric steel, segregation will take place only in negligible quantities as the rate of cooling is too great to allow any extensive concentration.

On the other hand, if we adopt the conclusions of Professor Howe, segregation will be greater in electric steel inasmuch as carbon has an automatic tendency at being higher than in converter steel.

### INFLUENCE OF LARGE SULPHUR CONTENTS

It is a well-known fact that with sulphur contents up to 0.1 per cent the direct action on ductility and tensile strength is negligible. The only detrimental effect of sulphur is to cause red shortness, or cracking and checking if the steel has to be forged or rolled.

Neither the converter nor the electric furnace contemplate, to any great extent, the manufacture of steel castings which will later be forged. It ensues that higher sulphur contents in converter steel would not prove detrimental to steel castings especially if the manganese contents are properly graduated to offset any possible bad effect due to sulphur.

The only advantage of very low sulphur therefore seems to apply to the rare case of steel castings which have to withstand high temperatures.

### INFLUENCE OF LARGE PHOSPHORUS CONTENTS

Phosphorus is the element which is the most detrimental to steel as it creates brittleness under shock, and general cold shortness. It is the consensus of opinion that phosphorus contents should not exceed 0.08 per cent for all practical purposes. Between 0.05 per cent and 0.1 per cent the elongation and reduction of area are not affected to any great extent while the tensile strength increases. The readings of the testing machine are not therefore of any special value when the effects of phosphorus are considered. Cold bending tests, by use of a drop, are best suited to determine the quality of steel castings, but in the case of phosphorus we find results erratic and capricious and it seems that on this score the best factor to be considered after chemical analysis is the reliability of the producers of the steel.

In the present controversy it must be admitted that the electric furnace has the advantage of being able to use such raw material as will insure low phosphorus contents, but accumulation of phosphorus is very slow in the converter process and the chances of picking it up from fuel, while melting, are very remote. It is, therefore, just to say that converter steel while higher in phosphorus contents than electric steel, more than come within the ordinary limits of safety.

It has been regretted that there did not seem to be any ready market for electric steel castings. The arguments given in the present article might provide a good basis of explanation.

Tropenas Converter Co.,
New York City.

## Award of the Willard Gibbs Medal to Ira Remsen

At a banquet of the Chicago Section of the American Chemical Society, on May 15, the Willard Gibbs gold medal was presented to Dr. Ira Remsen, a founder and former president of Johns Hopkins University. Founded by William A. Converse of the Dearborn Drug and Chemical Co., Chicago, the medal has been awarded before to three other prominent chemists.

In an address on "The Development of Chemical Research in America" Dr. Remsen spoke of the necessity of studying chemistry for the love of the science and commented at some length on results obtained by now prominent chemists who at one time had been his students. Among those at the speakers' table were President George E. Vincent, University of Minnesota, Professor Harry McCormick, Armour Institute of Technology, President Abram W. Harris and Dr. William A. Noyes, Northwestern University.

**Electrolytic Zinc.**—The Borchgrevink electrolytic process for the treatment of zinc ore is to be tried on a larger scale in Norway. Mr. Borchgrevink has succeeded in making his process a success with zinc ore in lime stone containing less than 6 per cent. zinc, so he has been working so far only on a small scale (200 kilograms per doz.). A factory is being built near Kristiania and is expected to be ready in September, with a capacity of one ton per day.

## Paul Héroult

Paul Héroult, the famous pioneer of the electrometallurgy of aluminium and steel, died in Paris on May 9, at the age of only fifty-one years. He had been in poor health for the last few years, suffering from kidney trouble, yet to his many friends on this side of the Atlantic the news of his death came as a sudden unexpected shock.

Paul Louis Toussaint Héroult was born at Thury-Harcourt (Calvados, Normandy) on April 10, 1863. Since his grandfather lived in England he spent his youth's happy days partly in France and partly in England. He was educated at the Lyceum of Caen, Normandy, and later at St. Barbe in Paris, where he graduated in 1882, to enter the Paris School of Mines (Ecole des Mines). From 1883 to the beginning of 1884 he served in the French army and then returned to the School of Mines, but on account of the death of his father he was soon forced to quit his studies in order to conduct the business of his father's tanning works.

However, Héroult continued there his metallurgical researches. He was particularly interested in the electrochemical production of metals. He bought a small Gramme dynamo of 1.5 hp, which he replaced in 1886 by another small machine giving 800 amp at 15 volts. This machine was especially built for his aluminium process, for which he had applied for patents in the same year. In 1887 he became technical manager of the Neuhausen aluminium works of the Swiss Metallurgical Company, where his process is in use up to the present. He then started an aluminium plant in France, at Froges, Isère, for The Société Electrometallurgique Française. About the same time he made two trips to this country, where meanwhile, independently of, and simultaneously with him, Charles M. Hall had worked out what was essentially the same process for electrolytic reduction of aluminium and had started the works of the Pittsburgh Reduction Company.

THE LATE PAUL HÉROULT

After his return to France, Héroult assumed the management of the Froges works, but after the erection of a larger water-power plant in La Praz, Savoy, he became general manager of these new La Praz works. In 1892 the power developed at La Praz was 3000 hp, which was increased to 13,000 hp in 1895.

Héroult's aluminium furnace, which by the addition of a tap hole was rendered a continuous apparatus, became in his hands the instrument for numerous further researches. In it he made the first commercial calcium carbide produced in France. In it he undertook for the Société Electrometallurgique de Froges, the manufacture of artificial corundum, ferrosilicon and ferrochrome, and thus he was led to the researches on the use of the electric furnace in the iron and steel industry to which the balance of his life was chiefly devoted.

In 1904 Héroult came again to the United States to attend the St. Louis World's Fair, and since that time he resided alternately in this country and in France. The American rights of his electric steel furnace which made rapid progress in Europe, were acquired in 1910 by the United States Steel Corporation. With respect to the reduction of iron ore in the electric furnace, Héroult assisted Dr. Haanel's Canadian government investigation at Sault Ste. Marie and also helped in the early work of the Noble Electric Steel Company at the place named in his honor, Heroult-on-the-Pit in Shasta County, California. He later became consulting engineed for the new works of the Southern Aluminium Company, in course of erection at Whitney, N. C., but his failing health forced him to retire. He went to Paris, where he lived the last few years. He was married twice and leaves a widow and five children.

Especially through his connection with the aluminium industry Héroult accumulated a very considerable fortune. Many honors were bestowed on him; the Institute of Technology of Aachen, Germany, conferred on him the honorary degree of Doctor of Engineering; France gave him the red ribbon of the Legion of Honor and the Grand Lavoisier Medal. He had many ardent friends in this country and was a member of the American Electrochemical Society and The Chemists' Club. At the meeting of the New York Sections of the American Electrochemical Society, the American Chemical Society and the Society of Chemical Industry, held on May 22, Dr. C. A. Doremus spoke as follows in proposing a resolution in honor of Héroult's memory:

"Voyagers of old made new maps of the earth. Héroult, the pioneer in metallurgy and engineering, has staked out new fields for his successors to develop. The visions of linking the two great oceans across the Isthmus have only been realized after centuries, but in the span of a quarter of a century Héroult brought to successful practice two epoch-making discoveries. Nor did he rest content with these.

"He showed us how to release aluminium from the bondage in which it has been held for geologic eons; he utilized it in the arts; he gave it to us for the treatment of steel and then carrying forward his intelligent use of the electric current not for electrolysis this time, but for thermic results, has founded a new art in the purification and treatment of the metal for which his age is named.

"Héroult was original, imbued with the ardor characteristic of youth, he was intrepid, resourceful, persistent, and reduced his inventions to practice, in ways that brought him international recognition. And then what a man!

"Whoever had the good fortune to meet him must have been impressed with his modesty, yet also with his latent power; with his cosmopolitanism, yet pride in his native land; and above all with that genial nature that endeared him to his friends and to professional brothers."

A resolution was adopted conveying to the widow and children the most heartfelt sympathy of the members of the three societies and the assurance of their esteem and affection for Héroult as a man, their gratitude to him for the wonderful inspiration he gave to all, working as he did for science and industry.

An appreciation of Héroult as a pioneer of electrochemistry will be found on our first editorial page.

# A Study of the Annealing Process for Malleable Castings

BY OLIVER W. STOREY.

This article gives the results of experimental work carried out by Mr. E. L. Leasman under the author's direction at the Chemical Engineering Laboratories of the University of Wisconsin. Although these experiments were preliminary in nature as a basis for extended work, interesting results were obtained.

Malleable cast iron is a product of importance. The annual production of the United States is over 1,000,000 tons. And yet, in such an important industry scientific progress has been slow. Each malleable iron plant makes its product under different conditions, and, as a result no two products are exactly alike except that all usually have to meet standard specifications.

The lack of scientific knowledge of this industry is made evident by the sparsity of the literature. The only book on this industry known to the writer is Richard Moldenke's recent work, "The Production of Malleable Castings." In the preface he states, "of the closely held secret processes of the great iron industry none can rank with the production of Malleable."

The first record of the process is by Reaumur, in 1722. It is probable that the malleablizing process was practiced much earlier, but, no doubt, it was like so many of the earlier industries, and was a secret which was handed down from father to son.

The pioneer manufacturer in this country was Seth Boyden, of Newark, N. J., who, although he did not discover the underlying principles involved, recorded his experiments. These are the first we have and he deserves special credit since they were made at a time when scientific experimentation on industrial problems was frowned upon.

Malleable iron occupies a position between ordinary cast iron and cast steel. It has a higher tensile strength than cast iron, but not as high as that of cast steel, while its resilience is superior to either.

The method of producing malleable castings is fairly uniform throughout the country. The white iron castings are packed in rolling mill scale in rectangular containers. These containers, either three or four high, are carefully luted up to exclude currents of air, placed in the ovens and heated to the desired temperature, being kept at the high point at least sixty hours. The total time of the annealing process is a week from one time of "lighting-up" to the next time.

The experimental work was carried out to determine the effect of the following variables upon the annealing process.

1. Packing materials.
2. Temperature of annealing.
3. Time of annealing.
4. Rate of cooling.

This was undertaken as a metallographic problem. All specimens were studied with the microscope which showed the structural changes.

In making malleable cast iron, white cast iron is used for the hard castings. This white iron must analyze to within certain limits to insure proper annealing. It is then annealed at the proper temperature, usually between 750° and 900° C., depending upon the practice, for about 60 hours, after which it cools slowly.

The structure of such a white cast iron is shown in Fig. 1. The two constituents shown are the white cementite and black pearlite, which is an eutectoid of ferrite and cementite. The cementite or iron carbide, $Fe_3C$, is present in two forms; first, as excess, and second, associated with ferrite as pearlite.

After being annealed at the proper temperature and slowly cooled the interior structure is usually that of Fig. 2, ferrite and temper carbon, with an outer shell that may vary from a pure iron to a high carbon steel. Fig. 3 is the fracture of a test lug, showing the black heart with an outer bright steel rim.

It is evident that the formation of the malleable structure of ferrite and temper carbon is due to the breakdown of the iron carbide into its elements, iron and carbon, at the annealing temperature, according to the following equation:

$$Fe_3C + \text{heat} = 3Fe + C$$

This reaction explains the formation of the black heart but not the rim structure. A different condition is necessary to produce a pearlite shell than to produce one of pure ferrite. Three different rims are shown in Figs. 4, 5 and 6. Fig. 4 is the rim structure of the fracture shown in Fig. 3, and shows a medium carbon steel area covered by a thin skin of ferrite. Fig. 5 shows an outer rim of nearly pure pearlite, while Fig. 6 shows one of pure ferrite.

The four variables mentioned determine the structure of the casting. The packing materials will affect the rim, while the time and temperature of annealing and rate of cooling will determine the interior structure, with only a minor effect upon the rim.

The white iron used for the experiments was kindly furnished by the Beaver Dam Malleable Iron Company. The material was in the shape of test bars ¾ x ¾ x 10 inches. Mr. W. G. Grimer, chemist for the above company, furnished the following analysis with the bars:

| | | | |
|---|---|---|---|
| Total (combined) carbon... | 2.60 | to | 2.70% |
| Silicon .................... | 0.65 | " | 0.70% |
| Sulphur ................... | 0.055 | " | 0.060% |
| Phosphorous .............. | 0.140% | | |
| Manganese ................ | 0.27% | | |

Fig. 1 is a micrograph of the white iron used. The structure shows a high percentage of pearlite owing to the low percentage of carbon resulting from steel additions to the melt.

The annealing furnaces used for these experiments consisted of two muffles electrically heated by resistance wire. A low voltage regulating transformer gave absolute temperature control.

All thermocouples used were calibrated frequently against a standard platinum, platinum-rhodium couple.

In order to carry on a larger number of experiments in this preliminary work a number of small containers were made. Several could be used in the furnace at the same time. These containers were made of 1½-inch pipe, cut long enough to take specimens 2 inches in length. They were then luted with fire clay except where caps and nipples were used. The serious objection to these small containers was that the oxygen of the air usually had access to the specimen.

### Effect of Packing Materials

The first variable to be studied was the packing material. It had been noticed that certain specimens of commercial malleable iron had an enveloping skin of steel (Fig. 5), others pure carbonless iron (Fig. 6), while others showed an intermediate structure (Fig. 4). It was thought that the packing material would determine the structure of the outer shell.

A large number of packing materials were used, including lime, sand, alundum, rolling mill scale, resistor carbon, manganese dioxide, cement, fine and coarse fire clay, iron oxide, alumina, fine graphite and carborundum.

The results obtained by the use of these various materials showed that their physical and chemical constitution influenced the skin structure of the annealed casting. The packing material had no apparent effect upon the interior in the American "black heart" practice.

The chemical composition of the packing material was a factor that partly determined the nature of the outer portion of the annealed casting. With the materials which were stable at the annealing temperature the structure was uniformly a layer of ferrite. With oxidizing materials a deep layer of ferrite was formed. It is probable that enough oxygen was liberated to decarbonize to a greater depth.

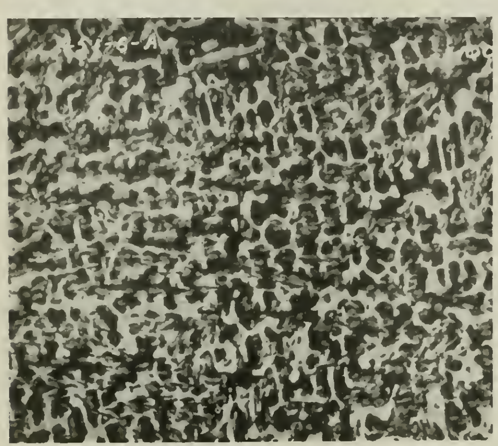

FIG. 1—MICROPHOTOGRAPH × 100

With carbon, charcoal, graphite and case carbonizing materials, a skin structure was formed which varied from a low-carbon to a high-carbon steel.

The physical structure of the packing materials also affected the malleable skin structure. Materials which were loose and porous and allowed a free circulation of the air showed a ferrite exterior. Without the oxygen of the air the structure of the exterior portion did not differ from the interior. This was best illustrated by the following experiments.

Brass turnings were used as a packing material in one of the containers. The brass fused at the annealing temperature and completely inclosed the specimen, preventing the oxygen from coming in contact with the exterior of it. Although a normal malleable structure was formed in the other specimens annealed in the same heat, the temper carbon extended to the brass coating which had formed on the specimen.

That the chemical composition of inert packing materials has little effect on the rim structure is evident from samples of commercial iron. Specimens from various plants using mill scale as a packing material showed a rim structure varying from pure ferrite to a high carbon steel. It is probable that the atmosphere of the furnace and the looseness of the packing rather than the chemical action of the scale determined the rim structure.

The experiments were not carried far enough to determine under what conditions the various degrees of carbonization could be obtained. Even if results were obtained these could hardly be comparable with those obtained in malleable practice. The atmosphere of the experimental furnace was highly oxidizing as compared with that of the commercial furnace. The small containers also allowed a quicker penetration of oxygen than those used in commercial practice. The probable exception was in the use of unusual materials such as case carbonizing mixtures.

But with materials such as mill scale, sand, clay, cinders, ashes, etc., the exterior structure will depend upon the composition of the atmosphere in the furnace, upon the annealing temperature, the method of packing, and the rate of cooling.

The writer recalls one malleable plant where scale is regularly used when the furnaces are running at the normal rate. But when a rush comes anything within reach is used as a packing material, usually ashes and cinders. No difference in structure is apparent between the two malleable products.

In another plant brick dust is replacing scale with no apparent change in structure. Large castings are annealed by merely heating in a muffle, care being taken to prevent excessive oxidation. The structure is the same in all cases, consisting of an exterior layer of ferrite, or pearlite, or both, and an interior of temper carbon and ferrite.

The skin structure, when a neutral atmosphere is used, does not differ from the interior since the breakdown is the same throughout the specimen. This was shown by the specimen annealed in brass. This shows that a slightly oxidizing action is necessary to secure a steel rim and that either a too highly oxidizing or a neutral atmosphere will give a ferrite or a ferrite and temper carbon rim, respectively.

The rate of cooling also has a slight effect upon the skin structure. A slow rate of cooling tends to result in a ferrite rim. This will be discussed later.

Where a case carbonizing mixture was used as the packing material the rim resembled the original iron (Fig. 11), since some of the excess cementite remained undecomposed. This structure will also be discussed later.

A peculiar rim is shown in Fig. 12. Here two steely strata are seen with a ferrite structure between them. Only one specimen showed such a structure.

The following conclusions may be drawn:

1. The packing material does not influence the interior of "black heart" malleable cast iron.

2. The ordinary packing materials do not directly affect the skin structure of malleable cast iron.

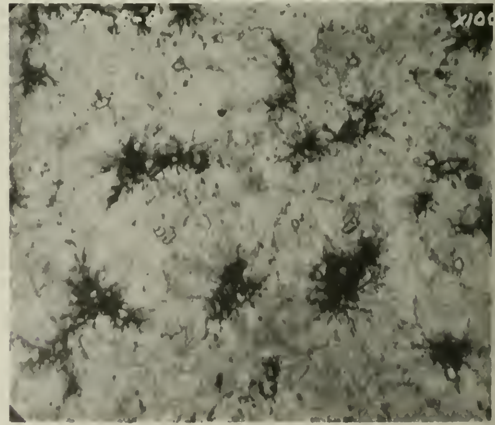

FIG. 2—MICROPHOTOGRAPH × 100

3. A loose packing material allowing a free circulation of oxidizing gases will result in a carbonless rim.

4. A slightly oxidizing atmosphere will result in a steely rim.

5. A neutral atmosphere will result in a rim having the same structure as the interior of the iron.

6. A slow rate of cooling will tend to result in a rim of ferrite.

### Effect of Temperature of Annealing

A number of experiments were run to determine the most effective annealing temperature for iron of the analysis given, where the time of annealing was 50 hours and the cooling to 250° C. took 50 hours.

| *Experiment No.* | *Annealing Temperature* *Deg. C.* |
|---|---|
| 4 | 815° |
| 5 | 760° |
| 6 | 700° |
| 7 | 730° |
| 9 | 840° |
| 10 | 790°–800° |

### Results

The specimens annealed at 700° were too hard to saw though slightly malleableized.

The specimens annealed at 730° were sawed with difficulty. Upon examination with the microscope the structure had broken down slightly.

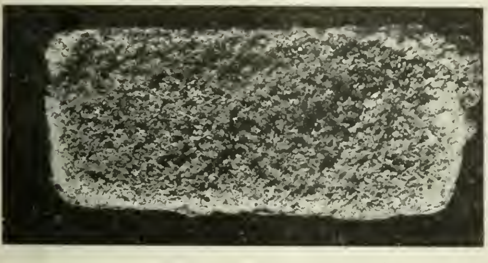

FIG. 3—MICROPHOTOGRAPH × 2½

The specimens annealed at 760° showed a partial breakdown of the cementite, as shown in Fig. 7.

Specimens annealed in experiments 4 and 10 showed but a partial decomposition of the cementite.

Upon annealing at 840° the carbide was almost entirely broken down (Fig. 8).

In one experiment the temperature was kept at 535° to 650° F. for 120 hours, but these specimens were too hard to saw.

In the first experiments an annealing temperature of 870° to 900° was maintained for 50 hours, and this resulted in a complete breakdown of the cementite. (Fig. 6.)

The effect of the temperature is an important factor. Not only does the time of the anneal, but also the quality of the resulting product depend upon the temperature. It is possible to cut down the time of the anneal by raising the temperature, but woe befalls those who do it. A poor product results. The lower the temperature of the anneal the better the product. The balance must be found between the increased value of the improved product and the high cost of the longer anneal.

Figs. 2, 6, 7 and 8 are micrographs of structures of malleable iron annealed at varying temperatures. Fig. 7 shows the result of annealing at 760°. The micrograph shows areas of cementite in a background of ferrite with a few particles of temper carbon. The dendritic structure of the cementite is visible. This shows that the cementite in the pearlite suffers the first breakdown and that the excess cementite is the last to dissociate.

By annealing at 840° the structure of Fig. 8 was obtained. Small particles of undecomposed carbide are still visible though the specimen is composed mainly of ferrite and temper carbon.

Fig. 2 is a micrograph of some commercial iron and shows small areas of cementite. Most commercial malleable iron shows such areas, indicating that the annealing was not entirely completed.

In Fig. 6 the structure is entirely ferrite and temper carbon, indicating that the breakdown at 870° was complete.

### Conclusions

1. With an annealing time of 50 hours the white iron furnished required an annealing temperature of 860° to secure a complete breakdown of the cementite.

2. Annealing at 740–760° for 50 hours resulted in a partial breakdown. By continuing the heat to double the above time it is probable that a complete breakdown could have been secured.

3. No decomposition could be observed in specimens annealed below 670°.

### The Effect of Rates of Cooling from the Annealing Temperature to 250° C.

In all malleable iron work one of the most important factors is the rate of cooling. In the anneal the cooling is slow, usually requiring from 40 to 60 hours. If the cooling is too fast a hard, brittle, steely structure results.

In this research the result of the different rates of cooling was noticed in the first three experiments. When the rate was slow, that is, the drop from 900° to 670° required 38 hours, the interior of the specimen showed an excellent malleable structure, ferrite and temper carbon. (Fig. 6). When the same drop in temperature required but 22 hours, the resulting interior structure showed ferrite, temper carbon and areas of pearlite. (Fig. 9.) When the time occupied but 15 hours the interior showed pearlite, temper carbon, and a small amount of ferrite. (Fig. 10).

From these data it was evident that the structure of the resulting anneal was dependent upon the rate of cooling. It was not only desirable to determine the most suitable rate of cooling, but also to obtain the critical range through which this cooling had to be slowest.

The $A_1$ temperature, 700°, was regarded as the critical point. At this point the transformation of austenite into pearlite occurs. The experiments were run so that the critical range was above 670°, allowing for a lag of 30°.

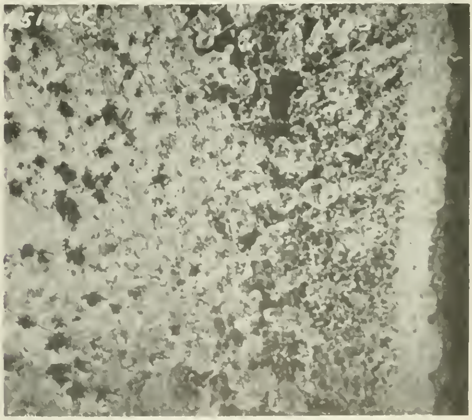

FIG. 4—MICROPHOTOGRAPH × 30

In experiment No. 11, the first of this series, the furnace burned out and the time of cooling was rapid, requiring 14 hours to drop from 870° to 250°. All specimens showed an interior of high-carbon steel and temper carbon similar to that of Fig. 10.

In experiments No. 12 to No. 16 the time of cooling from 870° to 750°, 750° to 670°, and 670° to 250° was varied.

From these experiments one conclusion was drawn. The rate of cooling from 670° to 250° had little, if any, influence on the structure. Though the evidence was inconclusive the work done so far indicated that the rate of cooling from 840° to 730° determined the re-austenite will be precipitated in that range.

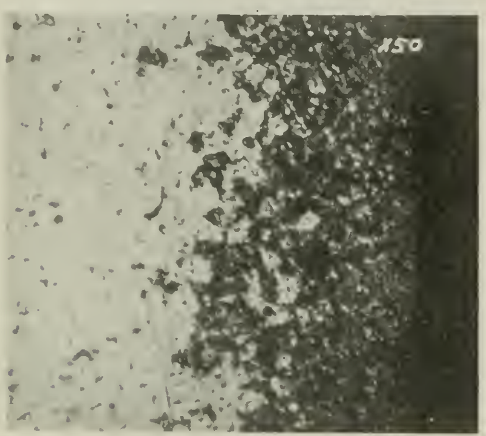

FIG. 5—MICROPHOTOGRAPH × 50

When the malleable iron made in these experiments was reheated for 10 minutes the carbon did not go into solution below 800° and form a steel with air cooling. A slight amount of carbon went into solution when heated for 1 hour at 800°. If the malleable iron was heated at 850° enough carbon went into solution in a few minutes to form a high-carbon steel. This experiment showed that the carbon could not precipitate out entirely above 800°, and that the critical range was below that temperature.

Specimens which had been heated to 900° and consisted of pearlite and temper carbon were annealed at 700° for various periods of time and cooled in the air. When heated to 700° for one-half hour part of the pearlite was decomposed and a narrow band of ferrite surrounded each particle of temper carbon. When heated for 2 hours about one-half of the pearlite was decomposed and the temperature resembled Fig. 10, though the outlines were not as definite. By heating the specimen for 5 hours at this temperature all of the pearlite was decomposed and structure again consisted of ferrite and temper carbon. This experiment would seem to show that the final breakdown of the cementite may occur above the $Ar_1$ point. At the present time the effect of heating at temperatures above and below 700° has not been studied.

It was noticed that particles of undecomposed excess cementite remained unchanged throughout these heat treatments showing that it was stable in comparison with the dissolved cementite.

If the temperature necessary to entirely decompose the iron, iron-carbide solution was below 800°, and if the reaction was negligible below 670° it was evident that a good structure could be obtained by holding the specimens at the critical temperature upon cooling for the correct length of time and then cooling at a quick rate. It was also evident that a good structure could be obtained by annealing at this critical temperature and cooling rapidly. This was done, and although the time required was longer, owing to the lower temperature, a good structure resulted.

The temperature of the final precipitation of carbon is probably dependent principally upon the silicon and manganese content of the iron. The lower the silicon content the lower the temperature at which the iron carbide is stable.* The proportion of these elements will determine the critical range of the iron.

### Conclusions

1. A fast rate of cooling after annealing results in a steely structure.
2. The critical cooling range is between 740° and 830°.
3. If the rate of cooling is sufficiently slow in the critical range all of the carbon in the undecomposed austenite will be precipitated in that range.
4. If the carbon is entirely precipitated in the critical range the rate of cooling below 700° has little effect upon the iron.
5. Very slow cooling will result in a ferrite rim.

### Time of Annealing

A number of experiments were run to determine the correct time of annealing at various temperatures. The results showed that a malleable structure was obtained in 36 hours at 870°. By raising the temperature to 985° the time was cut to 18 hours, while at 740° the necessary time was more than 70 hours.

Though the short, high temperature anneal looks attractive it is not practicable owing to several reasons. It soon ruins the furnace, burns the saggers, and results in a poor grade of malleable iron. The lower the temperature of anneal the cheaper the upkeep of the furnace and the better the iron. Though the best product results from the 740° anneal, this low temperature is usually prohibitive where cost must be considered, owing to the length of time.

### Reactions In the Annealing Process

A metallographic study of the specimens showed the successive reactions occurring in the process. The following data are significant in determining the reactions resulting in the malleable iron structure:

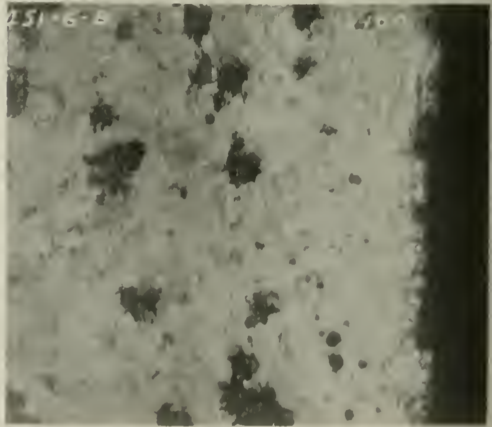

FIG. 6—MICROPHOTOGRAPH × 100

1. When the malleable iron was heated for too short a time or at too low a temperature and slowly cooled the structure consisted of ferrite, cementite and temper carbon. (Fig. 7.)

---

*Charpy and Cornu Compt. rend. 157, 901

2. By increasing the time at the maximum temperature or increasing the temperature the cementite areas were almost (Fig. 8) or entirely eliminated. (Fig. 6.) The structure then consisted of ferrite and temper carbon.

3. By annealing at the proper temperature to insure the breakdown of all of the excess cementite, but cooling rapidly from this temperature, the structure of Fig. 10 resulted. This consists of temper carbon surrounded by ferrite, in turn enveloped by pearlite.

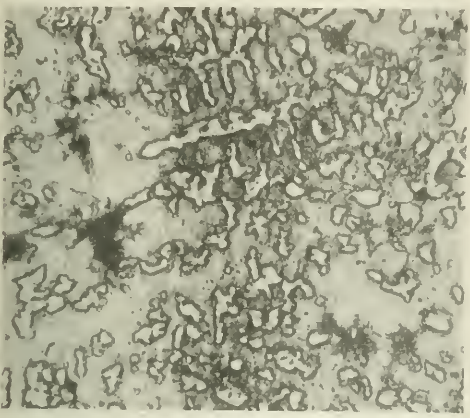

FIG. 7—MICROPHOTOGRAPH × 100

4. When the rate of cooling was slower than in No. 3 the structure of Fig. 9 resulted. This is similar to Fig. 10, but the pearlite areas are much smaller.

5. By annealing at too low a temperature and cooling rapidly the specimen consisted of areas of excess cementite surrounded by pearlite and small particles of temper carbon surrounded by ferrite.

6. When the malleable iron was reheated to about 800° the temper carbon started to go into solution.

7. It was possible to secure a complete decomposition of the dissolved cementite at 700°.

From these data the mechanism of the formation of the malleable structure could be deduced.

The white iron consisted of cementite and pearlite. When heated to the annealing temperature this pearlite went into solid solution as austenite.

It is a question whether the breakdown of the cementite occurs directly from the excess cementite or whether it occurs from the iron carbide dissolved as austenite. Though the research did not result in any definite conclusions, it seemed to indicate that the excess cementite did not break down directly, but that it first went into solution as austenite, from which the carbon was precipitated.

If the excess cementite of the white iron broke down directly the reaction should show some free graphite scattered in areas of cementite, since the decomposition would proceed uniformly throughout the carbide particles. Instead of a uniform breakdown and the scattered formation of temper carbon these cementite areas grow smaller as though they were being gradually dissolved, while the temper carbon forms in large patches. There is no indication of a direct decomposition of the excess cementite.

If the cementite in the austenite decomposes and deposits the temper carbon the ferrite liberated will dissolve the excess cementite. The presence of the nucleus of temper carbon probably causes a more rapid breakdown of the dissolved carbide.

In the specimens examined in which excess cementite remained owing to imperfect annealing, it was found that the cementite adjoining temper carbon areas was usually much smaller than that farthest away. Usually the area directly about the temper carbon was free from cementite. This would be the result if the carbide in the austenite decomposed. Owing to the liberation of the ferrite at the temper carbon the concentration of this consituent would be greatest there and the excess cementite in the immediate vicinity would be more quickly dissolved than that farther away.

The stability of the excess cementite in the white cast iron is shown again in Fig. 11. This specimen was annealed in a case-carbonizing mixture and the exterior portion retained the greater part of the excess cementite. Temper carbon and ferrite were also present in this rim. The interior showed a good malleable structure. In this case it is probable that the carbon necessary to replenish the austenite due to the decomposition of the dissolved carbide was obtained from the carbonaceous gases of the case-carbonizing mixture instead of from the cementite areas. The temper carbon in this rim was not surrounded by ferrite, but was scattered throughout the cementite areas, showing that the latter was more resistant than the gases to the dissolving action of the ferrite liberated at the temper carbon.

The decomposition of the iron carbide in the austenite is not complete at the annealing temperature, but is probably complete at 700°. By cooling quickly from the annealing temperature the specimen consists of nearly pure pearlite and temper carbon, or, if a piece of good malleable, consisting of ferrite and temper carbon, is heated to the annealing temperature, part of the carbon is quickly redissolved to form pearlite. By then annealing at 700° all of the carbon may be reprecipitated.

This pearlite formation shows that the stability of the cementite dissolved in the austenite is a function of the temperature, which is determined more or less by the silicon and manganese ratio. The lower the temperature the less stable the iron carbide. The determination of the limiting temperature or where the cementite is completely unstable was not made, but is probably close to the eutectoid temperature, about 725° to 775°. By cooling slowly through this temperature range the iron carbide may be entirely decomposed and ferrite and temper carbon obtained.

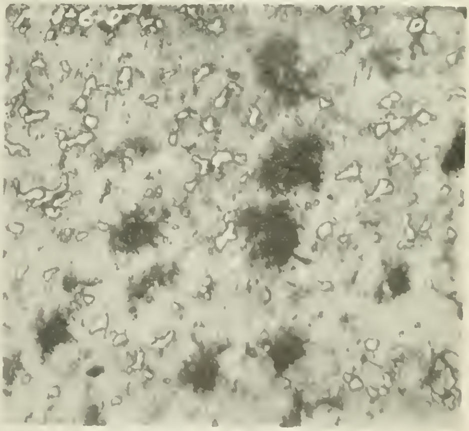

FIG. 8—MICROPHOTOGRAPH × 100

Since the cementite is unstable below this temperature the breakdown of the iron carbide may be possible below the $Ar_1$ point, but the reaction is slower since it is at a low temperature and the carbide is not in solution. Therefore, if the rate of cooling is slow until 650° or 700° is reached, the cooling may be more rapid to the room temperatures. This is corroborated by the experimental evidence.

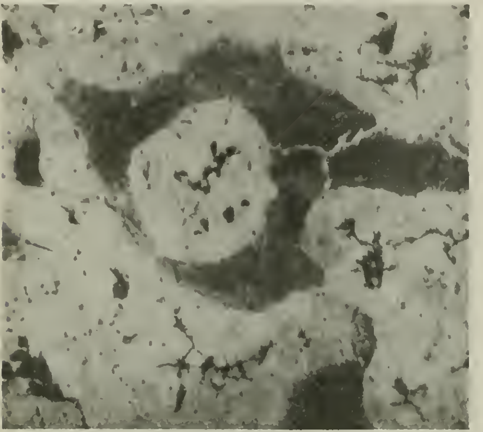

FIG. 9—MICROPHOTOGRAPH × 100

Where the cooling from the annealing temperature is too fast the iron carbide forms pearlite. (See Figs. 9 and 10.) Since the austenite about the temper carbon particles is richer in ferrite the rejection of ferrite takes place here and the pearlite forms furthest from the carbon.

The structure of the rim is also dependent upon the rate of cooling. If the carbon is oxidized from the surface to an extent which will result in a medium to a high-carbon steel, as shown in Fig. 5, and the rate of cooling is slow enough to prevent any pearlitic formation in the interior of the specimen, the cementite in the rim will probably be stable owing to the absence of carbon nuclei. If the rate of cooling is too slow even this cementite will decompose forming a lower carbon steel or a pure iron skin, as shown in Fig. 6. Areas of such partly decomposed pearlite are shown in Fig. 12.

The skin effect has been a much discussed problem. Several different explanations of the disappearance of the carbon, or the decarbonization of the rim of malleable iron, have been offered. Some hold that the carbon migrates to the interior and remains in the casting, while others claim that the carbon migrates out and disappears entirely from the casting. It is obvious that if the carbon migrates out and leaves the iron at the temperature used for annealing, it must do so in the form of a gas. An analysis of the gases formed during the annealing would indicate their nature.

In the hardening and annealing of steels care must be used so that the surface does not become decarbonized. Experience shows how easily and quickly the surface carbon is oxidized. This surface decarbonization is not alone a result of the action of oxygen according to the following reaction:

$$2Fe_3C + O_2 = 6Fe + 2CO$$

$$2CO + O_2 = 2CO_2 \text{ (with excess oxygen).}$$

The surface reaction may also be the result of the action of $CO_2$ on the iron carbide.

$$Fe_3C + CO_2 = 3Fe + 2CO$$

$$2CO + O_2 = 2CO_2$$

$$Fe_3C + CO_2 = 3Fe + 2CO, \text{ etc.}$$

The amount of decarbonization is therefore dependent upon the presence of oxygen and carbon dioxide.

This reaction may be applied to the annealing process. Since the castings are somewhat inaccessible to the furnace gases the reactions and the rim decarbonization are slow. Where the furnace gases have a large excess of oxygen the reaction is more rapid than where less is used. The slower the oxidation the more steely the rim.

Even with a carbon packing it would be impossible to obtain a steel rim at certain low temperatures owing to the equilibrium relations between $CO_2$ and CO. This equilibrium calls for more $CO_2$ at the lower temperatures, and for this reason a casting annealed at a lower temperature, 700–800°, would probably have a more decarbonized rim than one annealed at above 800°. Where a carbon monoxide atmosphere is maintained as in the case of the specimen annealed in a case-carbonizing mixture, no surface oxidation results.

Some experiments were run to determine the gases resulting from the annealing operation. The reducing nature of the gas was shown in a preliminary experiment where a specimen was annealed in cupric oxide. The oxide was reduced, resulting in a mass of metallic copper. Samples of gas, which were being given off by specimens, were then taken and analyzed.

The following gas was taken from a sample being annealed at 870°.

| | *Per Cent* |
|---|---|
| Carbon dioxide | 13.2 |
| Hydrocarbons | 0.0 |
| Oxygen | 8.8 |
| Carbon monoxide | 26.8 |
| By difference, Nitrogen | 51.2 |

A second sample was taken from one annealing at 980°.

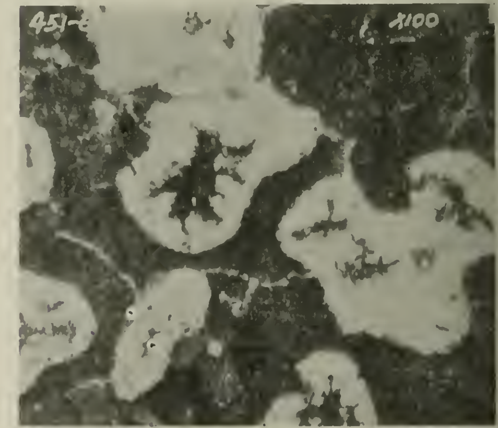

FIG. 10—MICROPHOTOGRAPH × 100

| | *Per Cent* |
|---|---|
| Carbon dioxide | 4.6 |
| Hydrocarbons | 0.0 |
| Oxygen | 3.4 |
| Carbon monoxide | 71.2 |
| By difference, Nitrogen | 20.2 |

The above analyses show that the carbon is removed from the casting as a gas, the composition of the gas depending upon the temperature and oxygen present.

### General Summary and Conclusions

1. This research has resulted in the affirmation of some of the established laws in the annealing of malleable cast iron, namely:

(a) That the packing material does not affect the interior structure.

(b) Slow cooling is necessary to obtain good malleable.

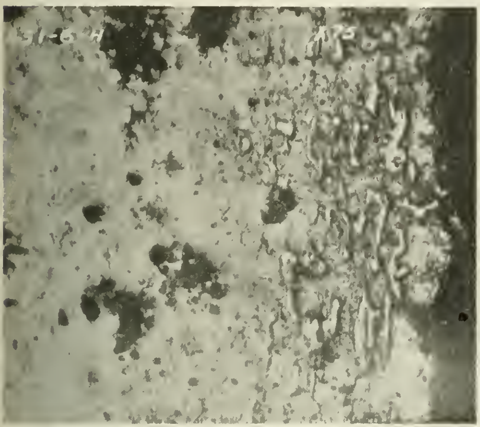

FIG. 11—MICROPHOTOGRAPH × 75

(c) A low temperature anneal gives a much better grade of product than the high-temperature malleable.

2. The conditions influencing the rim structure have been investigated.

3. The result of too rapid cooling has been studied, and is shown to result in a steely structure.

4. The breakdown of the iron carbide has been studied, and though present results are not final all seem to show that cementite does not break down directly, but decomposes from the solid solution or austenitic condition. This breakdown may be compared to the electrolysis or decomposition of a salt. While it would be difficult to decompose a salt in the dry state it is a simple matter to cause decomposition when dissolved in water. The ionic theory calls for a dissociation into ions when such a salt is dissolved in water.

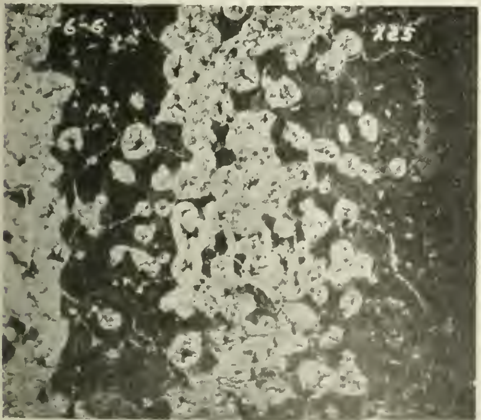

FIG. 12—MICROPHOTOGRAPH × 25

Cannot the case of the decomposition of iron carbide be compared to the decomposition or dissociation of a salt? The analogy is not perfect, but a comparison can be made.

5. The decomposition of the iron carbide is complete above the $Ar_1$ point of the iron-carbon diagram. Whether iron carbide is unstable below the $Ar_1$ point has not been determined.

6. The decomposition of the iron carbide is not complete at the annealing temperature, but is complete in a range of temperature just above the $Ar_1$ point, as given in No. 5.

The author wishes to express his appreciation of the thorough experimental work done by Mr. Leasman, and of the valuable assistance given by the Northern Chemical Engineering Laboratories in the preparation of this paper.

## Wheeling Creek Mine Explosion

### Carbide Lamps Freed from Suspicion

Gas and dust was the cause of the explosion which resulted in the death of Frank Hora at the Wheeling Creek Mine of the Lorain Coal & Dock Company at 2 o'clock, January 27th, 1914.

It was at first supposed that the residue from carbide lamps had caused the explosion; some of this residue was found in break-through 5, about 150 ft. from the center of the explosion. As a preliminary, pending the investigation, a temporary order was issued forbidding the miners of Wheeling Creek Mine to use carbide lamps. The local union passed a resolution demanding a thorough investigation and refused to go to work unless allowed to continue using carbide lamps.

In the meantime Chief Mine Inspector Davies, Deputy Inspector Gaffney, together with Safety Commissioner of Mines Roan, of the State of Ohio, aided by other deputies, officials and experts, were making a most searching investigation. It was soon demonstrated that as the residue left by the carbide lamps is merely slaked lime it could not be considered as a cause and it was proved conclusively that even had there been fresh carbide in the break-through it could not have had anything to do with the explosion as the break-through was dry. Carbide will not give off sufficient gas when exposed to the air to cause an explosive mixture or an ignitable mixture unless brought in contact with actual water. The moisture in the air is not sufficient to make enough acetylene to ignite. There can never be an accumulation of gas produced from carbide by moist air for the obvious reason that in order to produce gas any air which has given up its moisture to produce acetylene must move on and the acetylene goes with it. The careful investigation of the location of the carbide residue showed that as a matter of fact, this residue was shut off from the butt entry in which the explosion occurred by a substantial brattice, the residue being located within 3 ft. of the adjoining butt entry in break-through 5, and, as before stated, with a brattice between it and the butt entry in which the explosion occurred.

When these facts became apparent a meeting of the local union was called. The order prohibiting the use of acetylene was rescinded by the chief mine inspector, his deputies and the Safety Commissioner. The investigation into the actual cause of the explosion continued. The work of the Ohio mine inspectors and the Safety Commissioner was supplemented by an investigation conducted by Mr. J. W. Paul of the U. S. Bureau of Mines. It was found that the explosion was caused by an accumulation of methane (fire damp) intensified by dust.

# Determination of Carbon in Iron and Steel

## Direct Method

BY W. D. BROWN.

The essentials for complete combustion are an initial temperature of the furnace of about 1800° F., the burning of the metal in nearly pure oxygen, and an unlimited supply of the latter during combustion. If the metal is pushed into the furnace and a slow stream of oxygen started, combustion will begin before all the air has been displaced and will be in a mixture of air and oxygen; possibly the combustion of the iron will be complete before the oxygen has completely displaced the air and the only work remaining for the oxygen is to displace the carbon dioxide in the tube. When the combustion begins, oxygen should be supplied as fast as the iron will combine with it, that the temperature may be raised to the highest point; about 3000° F. will be momentarily obtained and all the carbon will be oxidized. These requirements of starting combustion in oxygen and an unlimited oxygen supply have been met in the method described below. In addition the supply of oxygen has been made automatic.

*Apparatus.* The electric furnace contains a silica tube ⅞″ in diameter and 24″ long; in it ignited asbestos is loosely placed from the exit end to within 3″ of the middle of the furnace; this acts very well as a catalizer, and is necessary when burning pig iron, at least. Oxygen is obtained in 100 ft. cylinders on which is a pressure reducer and regulator which supplies oxygen at a pressure from 1-3 lbs. as desired. The regulator is connected to brass piping containing four tees and globe valves for four electric furnaces (more could be added as desired), thereby one tank is used for the four furnaces. Oxygen enters the silica tube through one hole of a two-hole stopper. In the other hole is a 12″ copper or glass tube, ¼″ outside diameter; on the end of the tube is a No. 00 single hole rubber stopper. Through this stopper and tube a plunger rod of No. 9 nichrome wire, 24″ long, to which is riveted a sheet of nickel about ½″ diameter, is inserted. This is used to push the boat into the hot part of the furnace after the oxygen has displaced the air and while the current is flowing, and can be made in any laboratory; the No. 00 stopper can very well be replaced by a small stuffing box, in which case the copper tubing is shorter. The oxygen being free from $CO_2$, no purification is necessary. Both ends of the silica tube are cooled by copper water jackets.

The exit end of the tube is connected by a rubber stopper to a glass stopcock, which is used to regulate the flow of gas. The stopcock is connected to a 5″ drying tube filled loosely with phosphoric anhydride. It has been found that a zinc tube is not necessary, as the sulphur trioxide fumes are caught by the asbestos and phosphoric anhydride.

The drying tube is connected by a rubber tubing, on which is a pinchcock, to a Vanier potash bottle. This bottle contains a solution of potassium hydroxide (purified by lime) of 100 grams per 100 c.c. water. The inner tube is filled with phosphoric anhydride and a covering of glass wool placed thereon. Filled in this manner, the bottle will last for 100 determinations. The part which fails first is the phosphoric anhydride; a solution will form in the bottom of the drying chamber and will gradually grow until there is no more dry anhydride; this marks the life of the bottle.

On the construction of the Vanier bottle depends the success of the method; it must be so made that a speed of 400 c.c. per minute may be obtained without the gases passing out the lower end of the inner coil, which can be done if the lower end points or slants downward instead of being horizontal. The exit end of the coil should also be opposite the entrance to the drying chamber to prevent the splashing of the potassium hydroxide solution into the phosphoric anhydride. (Such a bottle is supplied by A. H. Thomas Co.)

*The Method.* A blank is first run in the following manner. With all connections closed, the oxygen is turned on the line and the pressure varied until three lbs. are obtained. One or more bottles are then connected to the furnace or furnaces and the stopper inserted in the entrance of the silica tube, the stopcock in the bottle is then turned, the pinchcock opened, and the globe valves from the oxygen line opened full. Oxygen should then pass through the bottle at a rate of approximately 400 c.c. per minute, the pressure in the line dropping to 2 lbs. If the speed of the gas is not as great as this, the reducing valve should be so regulated as to increase the pressure. It may happen that one bottle will go faster than the other; in that case, the stopcock at the exit end of the furnace is to be partially closed so that all bottles have the same speed. When this condition has been obtained,—the right pressure in the oxygen line and the stopcocks just right, no change is made until it is necessary to renew the bottle or tank. The stream of oxygen is continued for five minutes, the oxygen is then shut off at the globe valves on the oxygen line and, as soon as the flow of gas slackens in the bottle, the pinchcock on the rubber tubing leading to bottle is closed and, when the flow has completely stopped in the bottle, the stopcock is turned, the bottle is removed and weighed, preferably with a tare. This is repeated until the variations between weights is not more than three decimiligrams.

For the actual test, 1.36 grams of steel between 20 and 60 mesh or half gram iron, are weighed and transferred to a groove in alundum contained in a nickel boat. The bottle is connected to the furnace as above and the stopper turned, the pinchcock being closed. The boat is placed just within the silica tube, the two-hole stopper carrying the pusher is then inserted in the tube, the pinchcock opened and the oxygen turned on full at the globe valve. Oxygen then passes through at the rate of approximately 400 c.c. per minute; if the rate varies perceptibly from this it can be regulated by stopcocks at exit of silica tube. After gas has passed through for one minute, the boat containing the drillings is pushed into the center of the furnace by shoving in the nichrome wire mentioned before, while the current of gas continues. In about one minute the drillings have become heated sufficient to burn freely and combustion then is very rapid, being complete in twenty seconds. During the combustion an unlimited supply of oxygen is at hand, as the globe valve is open full and the regulator is set for a definite pressure. The oxygen then passes through to sweep out the carbon dioxide formed, five minutes after the boat is pushed back being sufficient. The globe valve is then shut off and, when the flow of gas has slackened, the pinchcock is closed, followed by the closing of the stopcock as above described. The bottle is disconnected and weighed; increase in weight in grams, multiplied by 20 gives % C. when 1.36 grams steel has been used.

In routine work, one analyst weighs up four (or less) tests, places boats in furnaces and starts the gas flowing. During the one minute's wait, he examines stoppers, etc., for leaks, then pushes boats back and leaves furnaces for other work, returning in five minutes for the completion of the determination. This method can be used for the determination of carbon in steels ranging from 0.07 per cent to 1 per cent carbon, as well as on pig iron. Not only is the accuracy greater than with color determinations, but the time required for analysis by combustion is less than by color.

Duquesne, Pa.

# A Convenient Method for Handling Chemical Solutions in Quantity

BY C. C. PHELPS, M.E.

When acids and other chemical solutions of a corrosive nature must be lifted or conveyed from one place to another, the relative advantages of different methods of accomplishing the desired result cannot be decided on the questions of initial or operating costs alone, for the service may be so severe on certain types of apparatus as to render them practically useless in a short time. Frequent delays for repairing may also occasion great losses due to the stoppage of manufacturing processes. Ordinary reciprocating and rotary pumps are often out of the question, even when constructed of special material of a non-corrodible nature.

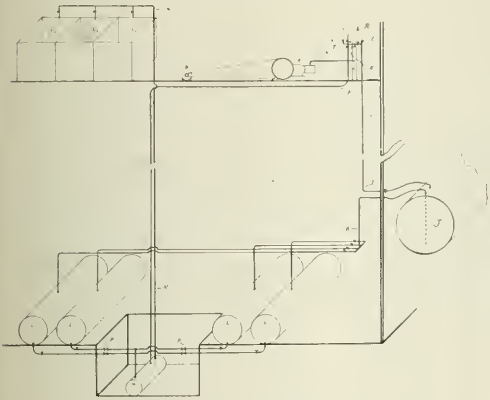

FIG. 1—SYSTEM FOR PUMPING ACIDS

A device known as a montejus, which is operated by either air or steam pressure, has been used to some extent for this purpose and is fairly satisfactory; but it is open to the objection that it has valves, floats and other moving parts in contact with the fluid. Other devices, using air or steam pressure, employ either the injector or siphon principle for their operation with more or less success, depending upon the requirements, but they, too, have certain limitations in practical use.

For handling chemical fluids in large quantities the method illustrated herewith has certain advantages which will be apparent from the description. The system illustrated in Fig. 1 is in use in a large Massachusetts textile mill, for raising heavy commercial oil of vitriol to bleaching vats on the third floor of a building. Compressed air is used, not only for this purpose but also to empty the acid from the tank cars which are brought alongside of the building. The engineers in charge of this plant consider that the method which they have adopted is admirably adapted for its purpose.

Referring to the diagram, $O_1$, $O_2$, $O_3$ are lead-lined bleaching vats; they are partially filled with pure water, after which 100 gal. of the concentrated sulphuric acid is raised and added slowly to the water, the contents being stirred while the acid is being added; then a small quantity of hydrochloric acid is added by hand from a carboy, after which the bleaching solution is ready for use.

Located near the vats is an air compressor *A* driven by a 2½-hp belted motor *B*. The compressor cylinder has a displacement of 15 cu. ft. of free air per minute and operates normally at 40 lb. per square inch air pressure. The compressor, gauge, receiver and controlling valves are shown in the photographic view, Fig. 2.

The compressor discharges into a length of pipe *C* of large diameter, which acts as a receiver to steady the pressure in the line. Gauge *Q* indicates the air pressure in the line. Two air lines, *I* and *F* lead from the receiver. By closing all valves on the left of the receiver outlet and opening valve *R*, pressure is put on pipe line *I*. The latter line leads to a connection whereby air pressure can be put on the tank of an acid car *J*. Safety valve *E* is set for 15 lb. per square inch, so no pressure in excess of this amount can be put on the car tank. The car tank's outlet is coupled with pipe *K* leading from the outside of the building to four heavy iron reservoir tanks *L* in the basement of the mill. Each of the tanks *L* has a capacity of 3,500 gal. and is provided with air vents. With an air pressure of 15 lb., it requires about two hours to empty the car, capacity of which is usually about 5,000 gal.

Pipes lead from the bottom of the reservoir tanks to the top of a 100-gal. iron supply tank *M* placed a few feet below. In each of these connecting pipes is a check valve *P* to prevent the acid from returning to the large tanks. Leading from the top of the small tank is the air pipe *F*. Normally this serves as a vent, allowing the acid to flow into the small tank and fill it. When a charge of acid is wanted, this vent is closed by a valve *S* near its outlet *G* and air pressure is put on this line by opening valve *T*. The acid immediately begins to flow from the bottom of the 100-gal. tank up pipe *N* to the bleaching vat, a height of about 40 feet.

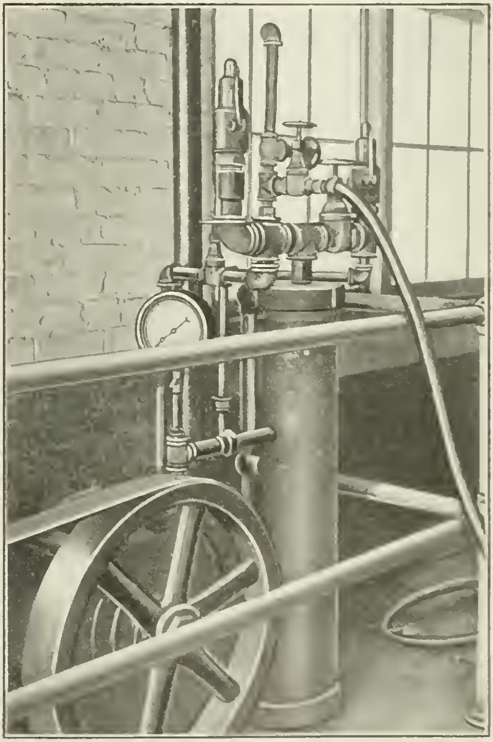

FIG. 2—COMPRESSOR RECEIVER AND CONTROLLING VALVES

About five minutes is required ordinarily to pump the 100 gal. wtih an aair pressure of 40 lb. Saafety valve *D* is set for 50 lb. per square inch. A short length of hose, *H*, connected to the air system, is used for cleaning and similar purposes.

With this system there is no mechanism to come in contact with the acid and get out of order. Everything is simple. When a charge of acid is wanted, the motor is started by simply throwing over the starting switch; then the proper valves are opened. The charging tank will not deliver more than a hundred gallons at a time, although less than that quantity could easily be obtained by shutting the valve at the vat at the proper time; the air pressure on the tank being constant, the rate of acid flow will, likewise, be constant, and the quantity of acid lifted in a given time will, therefore, be proportional to the time required for raising it. Pressure is put on the line only when actually pumping, hence the economy of operation is marked. The air pressure is on only the small tank and the lines leading to and from it. The larger tanks are never under air pressure and hence any trouble that might develop through leakage in such large tanks is avoided. The acid, being in concentrated form, does not cause any trouble from corrosion in the iron tanks or pipes, as might occur with dilute acid.

The flow of acid by gravity from the reservoirs to the small tank is entirely automatic and reversal cannot occur. No attention is given to the apparatus in the basement, the entire control being where the acid is used. The extreme simplicity of the arrangement described above ought to suggest its use for a large number of industrial processes, perhaps with modifications to suit each case.

Weehawken, N. J.

## Sixth International Congress of Mining, Metallurgy, Engineering and Economic Geology

### London, 1915

The Sixth International Congress of Mining, Metallurgy, Engineering and Economic Geology will be held in London from Monday, July 12, to Saturday, July 17, 1915.

An Executive Committee has been formed with Arthur Cooper, LL.D., as chairman; Sir William E. Garforth, LL.D., as vice-chairman; Sir Hugh Bell, Bart., D. C.L., LL.D., as honorary treasurer. Mr. G. C. Lloyd is the general secretary with offices at 28 Victoria street, London, S. W.

There will be four sections, section 1 being devoted to mining (coal mining and metalliferous mining); section 2 to metallurgy (chemical metallurgy and physical metallurgy); section 3 to engineering; and section 4 to economic geology.

Members of the Congress may be:

(a) Honorary members and the official delegates of foreign states.

(b) Supporters of the Congress—that is, members who subscribe not less than £5 ($25) to the Congress fund.

(The above will be entitled to attend all meetings and to receive all publications of the Congress.)

(c) Ordinary members, who pay a Congress fee of £1 ($5), which entitles them to registration in any one of the four sections, to attend all meetings, and to receive the Proceedings of that section in which they may elect to register. They may register their names in, and obtain the Proceedings of the other Sections by making a further paying of 5s. ($1.25) for each section.

The Congress fee for ladies is 16s. ($4).

---

## The Development of Modern Cyanide Practice

BY C. M. EYE., E.M.

In reviewing the rapid advance of the cyanide process for the recovery of the precious metals, one is most impressed by the broadened field of its application to-day as compared with that of the early days of the process. Many of us can remember when its successful application was limited to clean, porous, well-oxidized gold ores, the treatment being by leaching. The primitive method consisted of crushing dry to as coarse a mesh as possible, usually ¼-in. size or coarser, charging dry into shallow tanks with no attempt at separation of fines, and then leaching. The first wetting was by solution put on from below, followed by downward flow of solution, closely followed after the proper period by weak solution, and in this turn by water wash. The principal precaution taken was to avoid the separation of fines or slimes into a layer or layers at any stage of the treatment. The writer's first experience was obtained in a plant of this character, where, in spite of the presence of considerable clay in the ore, better than 90 per cent extraction was obtained regularly.

Following such direct treatment, the next logical development was its application to the tailings from other processes, notably amalgamation, and in this a much greater variation of practice developed. The treatment generally involved double handling, in order to rid the tailings of excess moisture, break up slime layers and render them permeable. In those days, since separate slime treatment was expensive and unsatisfactory, as large a proportion of slime as possible was handled with the sands by leaching. This rendered double handling almost unavoidable. The results on sand were poorer than if the slime had been kept out, but it was a case of choosing the lesser of two evils.

In many cases, however, direct filling and drainage was practiced, with poorer results, it is true, but at less expense. More slime had to be eliminated in this case; if not by previous classification, then in arrangements for securing overflow of slime and excess water as the tanks filled, by superimposed rings in the center as in South African practice, or by plugs and drains in the sides. Of course, the moisture content could not be reduced to as low a figure by direct filling, nor was the charge left as pervious for leaching, being packed after draining. Another difficulty encountered in this method of treatment, more pronounced than in others, was that of aeration to secure the oxygen necessary for extraction. Frequently preliminary treatment was followed by transfer and additional leaching in order to obtain additional oxidation and aeration. Attempts were made to introduce air from the bottom, but these usually resulted in channeling. About every known oxidizing agent was used, first and last, to artificially supply this necessary element, but were usually abandoned because of cost, inefficiency or deleterious effect on solution. The practice of using artificial oxidizing agents has therefore practically gone out, through aeration of solutions now fulfilling this function.

### Steps in Mechanical Development

The mechanics of the earlier developments were simple, the greatest development in connection with leaching methods being reached by the Blaisdell system of filling and emptying tanks by an excavator on the principle of a disk harrow, but this system was and is applicable only to large installations on account of its cost. The revolving sand filter for the preparation of sand for leaching is another extremely important development. These, with the simple but efficient Butters distributor, comprised the more important mechanical developments, until the invention of the submerged slime filter. This opened up an entirely new field for expansion, for it not only furnished a method of separating solution from slime much superior to the decantation method, until then followed for the treatment of slime unavoidably produced, but it led to the general adoption of fine grinding of sand, and the treatment of both together by agitation and vacuum filtration. The multiplicity of patented mechanical devices and methods using this principle led to so much litigation, however, that operators came to regard them all with mingled feelings of uncertainty and disgust, and came to regard vacuum filtration as something to be used when necessary, but to be avoided where possible. It was found also in many cases in practice that the net results from the use of filters were not so great as at first supposed on account of difficulties and expense of operation and upkeep.

Not that vacuum filtration has passed, or is likely to be relegated, by any means, for in many cases conditions are such as to make this the only practicable method of working; but the introduction of continuous treatment has made it possible to dispense with filtration by using other and more simple systems of separation. Foremost in this has been the continuous countercurrent decantation system, using thickeners for obtaining a low ratio of solution to solids, and involving the handling of solution instead of pulp with less power and less expense. The principal objection to this system is that while it affords an ideal means for very complete recovery of gold, it does not admit of as close recovery of cyanide solution without undue building up of stock solution, and for this reason has frequently to be followed by vacuum filtration to avoid heavy mechanical loss of cyanide.

### Upward Displacement in Slime Treatment

A system which rivals this and which is gaining ground, is based on the principle of upward replacement, the barren solution or wash being introduced at the bottom and displacing the solution which it is desired to remove. At first sight it would appear that diffusion would defeat the object sought, but when the displacing liquid is mixed with a thickened pulp at the bottom of a tank (this pulp being constantly added to by settling pulp from above and removed by drawing off constantly from the bottom), the displacement does take place with very little diffusion. It is probable that the proximity of the individual particles of the pulp in a thickened but thoroughly uniform mass, prevents the diffusive action which otherwise would occur. It is noticeable, also, that the diffusion is more pronounced between solutions of different chemical strength, and greatest between clear water and solution, as would be expected. While open to the objection that the use of slime-circulating pumps is essential, the system has several decided advantages: First, that in the replacement of gold-bearing solution, very little dilution of the solution takes place, enabling the metals to be recovered from a smaller bulk. Second, that only a small proportion of the gold is carried forward to the next stage with the pulp, as the solution going with the pulp is mostly barren solution that has been added. Third, that it affords a means of changing from solution of one chemical strength to another, or from water to solution or vice versa, with very little building up of stock or loss of chemicals. This latter point makes for the system two unique uses: First, in displacing water by solution from pulp where the preceding mill treatment is conducted in water, and, second, after cyanide treatment, in displacing solution by water for final discharge.

The extensive adoption of the practice of crushing and grinding in solution, dispensing with the amalgamation or other treatment, has obviated in many cases the necessity of close separation of liquid and solid before the latter enters the cyanide plant, a thickening to the desired degree of dilution for agitation being all that is required. It is here that the continuous countercurrent decantation system has its best application, it being possible to operate the whole plant with one closed solution circuit. But it is not always practicable to crush and grind in solution, owing to possible necessity of amalgamation to recover coarse gold not easily dissolved in cyanide, or necessity of concentrating or otherwise removing from the ore such constituents as would be destructive to cyanide in direct treatment. With these conditions, it becomes essential to remove as much liquid as possible from the pulp before it enters the cyanide plant, to avoid undue accumulation of solution and possible destruction of cyanide by soluble cyanides. It has even been found advisable to use vacuum filtration at this point, reducing the moisture to about 30 per cent, as against a usual 50 per cent by ordinary thickening. Even the 30 per cent remaining which has to be made up into cyanide solution of full working strength in the treatment, may cause a considerable accumulation of solution, and if the principle of upward replacement can be successfully applied here, with a resultant saving in cyanide, it will be a distinct step in advance. It is claimed by those introducing it that it is being so applied, but few data are available as yet as to this use. It is to be borne in mind that thickening is done at the same time, and in the same operation, though somewhat more expensively than ordinary thickening because of the necessity for operating a circulating pump in connection.

### Present Tendency in Agitation

In agitation methods, compressed air is the almost universal agent employed, both on account of its convenience of application, its value in aeration, and its cost, as compared with mechanical agitation, when upkeep of the latter is taken into account. Its use in air lifts as a means of pulp transfer is almost as nearly universal, and for the same reasons. The Pachuca is still the most popular air agitator, being in most cases now operated continuously in a series of several tanks. The extreme height at first thought necessary has been dispensed with in more recent installations, enabling these tanks to be used with less air pressure and equally good results.

Systems using circulating slime pumps are no longer in general use, owing principally to difficulty of keeping up the pumps, and the cost of operation. Modern slime pumps are being built, however, much superior to those of earlier days, with well protected bearings; and when run at proper speeds, and well cared for, with stuffing boxes protected at all times by clear water or solution under pressure, there is no good reason why they cannot be maintained. They allow of one important feature in treatment which is very beneficial, and that is the introduction of atmospheric air in abundant quantity, intimately mixed with the pulp, this air being free from the hydrocarbon compounds resulting from decomposition of lubricants in compression.

Probably the latest successful agitator to be placed on the market combines the mechanical agitator with the air-lift principle of the Pachuca. In fact, several machines have been devised lately on these lines, but with different methods of application. This method may be regarded as the present tendency in agitator construction.

In precipitation, the old, original zinc shaving method of extraction is still used generally in smaller installations and out-of-the-way places, on account of its simplicity; but the perfection of the zinc-dust method, its cleanliness and ease of operation when properly installed, and its better adaptability with solutions weak in cyanide has led to its adoption in the majority of new and larger installations. The newly developed method of precipitation by the use of aluminium is no doubt the most nearly perfect method yet devised. Cleanup and refining methods vary much with the practice in precipitation, but the washing and direct smelting of carefully screened precipitates in oil-fired tilting furnaces covers the majority of cases.

The extension of cyaniding to ores of gold and silver combined, then to straight silver-bearing ores, some of which are very complex, is perhaps the most wonderful feature of the development of the process. Facilities for fine grinding and thorough agitation with air were the principal factors in this. The record made in scores of modern mills makes the chronicle not many years since of a 60 per cent extraction at Chloride, Utah, on ore containing chloride of silver, seem like a tale of the Middle Ages. And that was a record in silver cyanide at the time. Indeed, it is hard to realize how this process has, in twenty-five years or so, displaced to a large extent amalgamation (becoming its chief assistant where it has not displaced it), relegated to the past chlorination and silver amalgamation, and reached out into every part of the globe until it is to-day the most generally recognized and applied of all wet metallurgical processes.

*Los Angeles, Cal.*

## Development of Alaska

The final passing by Congress and signing by the President of the Alaska railroad bill is of interest to the mining and metallurgical industry. The development of a country acknowledged to be rich in mineral resources has long been delayed due to the inability of interested parties and the government to agree on a system under which the public lands should be exploited. Coal lands in particular have been the bone of contention. It is expected that the railroad bill will now be followed by one providing for leasing of coal lands. The provisions may not be all that could be desired, but in the main they are favorable. Comparatively large acreages, 2650 acres, are to be leased, and all the coal therein contained is covered by the lease. Royalties are regulated, above a minimum of two cents per ton, by competitive bidding among the lessees. With the development of coal lands in Alaska there should come an increased interest in its other mineral resources, and the mining industry should develop largely.

## The British Aluminium Company

The fourth ordinary general meeting of the reconstructed British Aluminium Co., Ltd., took place on March 27th, when Mr. A. W. Tait, chairman of the company, presided. He said that the trading profits for the year and the proceeds of investments, together with the revenue from the Kinlochleven & Foyers Estates, amounted to £268,720 5s. 2d., as against £194,823 15s. 11d. in the previous year; and these results are by a long way the best ever accomplished by the company since its original formation in 1894. The increase in the net profits is entirely due to trading and is attributable to increase of tonnage, economy in cost of production and, to a still greater extent, to the higher prices prevailing during the year. These prices, however, had not been abnormal, but have only returned to a reasonable figure after four or five years' depression.

The revenue from the Kinlochleven & Foyers Estates shows a decrease of £906 6s. 8d., as compared with the previous year, which is almost wholly due to unusual expenditure connected with the village at Kinlochleven, which was necessary for the housing of the workmen. Additional plant has been put down at the Aluminium Works at Vigelands, Norway, from which an increased production for the present year is expected.

The large increase in the productive capacity of the company's aluminium works has made it necessary to correspondingly increase the capacity of the works for producing alumina. Last year the company acquired a half-interest in the works of the Bauxite Refining Company at Hebburn-on-Tyne, but the increase so obtained is not now sufficient to meet present or future requirements, and arrangements have been completed to acquire about 38 acres at Burntisland, Scotland, where the conditions of labor supply and shipping facilities are favorable. To ensure a good supply of bauxite a quantity was acquired from the Union des Bauxites and has been deposited on land in the name of the company. This will form a reserve stock, only to be used to supplement regular supplies from the subsidiary company. The company's rolling mills at Milton, Staffordshire, have been employed up to their full capacity during the whole year. The new mills at Warrington, Lancashire, have been completed, and work was partially begun there at the commencement of this month.

With regard to the accounts, the depreciation reserve had been increased from £100,000 to £150,000, and the reserve account from £80,000 to £130,000. The profit on the year's working, after making provision for the prior lien debentures and debenture stock, and making the requisite allotments to depreciation and reserve accounts, justified the directors in recommending payment of the full dividend on the preference shares and 5 per cent on the ordinary shares. This was the first time the company had paid a dividend on its ordinary shares since the reconstruction.

The report was unanimously adopted.

## Scotch Ship-Building

Although it is unquestionable that there is a considerable decline in the ship-building trade, yet the orders placed during 1913 will ensure that the depression will not be felt in Scotch yards for some time yet; and at present the Clyde output is quite satisfactory. The total Scotch launchings for January amounted to 19 keels of 30,812 tons, of which 11 ships totalling 22,272 tons were Clyde-built. In January of last year only five vessels with a total of 9,755 tons left the stocks on the Clyde, and although the output for this January does not include any large liners or naval vessels the general average for the month has been maintained.

Two ships launched from Scottish yards early in February are of unusual interest to marine engineers. One, the Mississippi, built by Messrs. Harland and Wolff at their Glasgow yard for the Atlantic Transport Line, is a twin-screw vessel of some 5,000 tons gross, driven by internal combustion engines of the Diesel type made by the Burmeister and Wain Oil Engine Co., of Glasgow, and is the largest ship of the kind hitherto built on the Clyde, although she is the first Messrs. Harland and Wolff have built for internal combustion engines.

The other ship is the Transvaal, of 4,383 tons gross, built by Messrs. Ramage and Ferguson, of Leith, for the East Asiatic Co., of Copenhagen, and is the largest steam vessel yet constructed at Leith.

## Blast Furnace Stoves

BY J. E. JOHNSON, JR.

In the third decade of the nineteenth century James Beaumont Neilson, who from plain beginnings had made for himself a distinguished position as a gas engineer and authority on matters of combustion, was consulted by a furnaceman as to the reason for the very unsatisfactory work of his furnace, particularly in Summer.

This started Neilson on a long investigation. Among other things he experimented with the use of preheated air on gas burners and on blacksmiths' fires and found that the effect was a marked increase in the brilliancy and intensity of the combustion. In 1828 he took out a patent on the use of preheated air in the blast furnace, but even after surrendering two-thirds of his patent to furnace owners he had the greatest difficulty in obtaining a chance to make a trial of the process.

Finally after several years of effort and after overcoming the most factitious and most unreasonable objections to changes in insignificant details such as the shape of the blast pipe he made a demonstration and while the increase in blast temperature was only 80 deg. Fahr. the results were so obvious that the system was at once adopted and higher temperatures obtained.

Then he was at once thrown into another difficulty—that of preventing the overthrow of his patent by a combination of Scotch furnace owners who took a pledge to break his patent virtually "by legal means or otherwise" in order to avoid the payment of his moderate royalty of 1s. per ton, though the saving effected amounted to 32s. per ton.

It is rather a relief to realize that such piracy, which we have been taught to regard as the product of our own times, flourished even in those "good old days."

It is still more pleasant to know that after innumerable trials which went thrice to the House of Lords, Neilson and his associates won, and that on the royalties he finally received he was enabled to pass the closing years of his life in comfort and leisure devoted very largely to what would now be called welfare work. The results obtained were probably very much beyond Neilson's most sanguine expectations, and within a few years the warm blast was used in producing by far the largest proportion of all the iron made. The reason for this saving so disproportionate to the amount of heat introduced by the warm blast will be explained in an article on thermal action of the furnace. We have here only to deal with the apparatus used for heating the air.

The first apparatus used was in all cases a nest of pipes of some sort in a masonry chamber, within which the gas from the furnace burned around the pipes while the blast on its way to the furnace passed through them. In early days these stoves were set on the top of the furnace, or if not immediately on top of it at the level of the top and just to one side, as has briefly been described in connection with boilers, so that the burning gas from the open furnace top could be drawn into them. This had the disadvantage that the cold blast had to be taken to the top of the furnace and the hot blast brought back to the bottom with the loss of heat consequent upon that journey, and as soon as the closed top was introduced the stoves were set at the ground level, with great advantages in first cost and in convenience.

The temperature to which the blast could be heated in these stoves was strictly limited by the fact that the pipes constituting the heating surface were rapidly destroyed if a certain temperature, found by experience, was exceeded by even a small margin, and if the stoves were fired while no blast was passing through them to cool them off, they might be completely destroyed in a period of an hour or two

To meet this condition the late Sir William Whitwell conceived the idea of applying to this service the regenerator previously invented by Sir William Siemens, which consisted of a pair of chambers filled with brick work, through which passed a great number of passage ways arranged to present as much surface as possible.

Through these passage ways of one chamber the hot waste gases of combustion were passed for an interval sufficient to heat the bricks to a high temperature; then the gas was cut off from this and thrown into the second chamber, and the air to support combustion was drawn through the first chamber, from which it absorbed heat by direct contact with the hot surfaces of the bricks. When a sufficient amount of air had passed to lower the temperature of the bricks below that which would impart the required temperature to the air, the gas currents were again reversed in relation to the chambers, the gas being put back through the first one and the air currents being drawn through the second.

For melting the crucible steel, the first purpose to which Sir William Siemens applied his invention, the hot air for combustion was drawn through the checker work under the action of the stack draft, the pressure within the checkers, therefore, differed by only a few inches of water from that of the atmosphere, and masonry construction throughout was sufficient for tightness under this difference of pressure.

In order to apply this system to the blast furnace, however, the chambers had to be so constructed as to withstand the pressure of the air after compression to the pressure required for the blast furnace, because obviously the blowing engines could not handle blast heated to a temperature of 1000 deg. or so. Therefore, the blast must be compressed first, and after heating must go directly to the furnace.

For this reason Sir William Whitwell built his stoves in the form of cylindrical chambers with a top either cylindrical or dome-shaped to prevent deformation under pressure. The bottom was flat because prevented from deforming by the weight of brick work upon it. The shell of these chambers was of iron (later steel) plate, riveted together air-tight and strong enough to resist the maximum blast-pressure expected.

There was also another change in the conditions as compared with those of the steel melting furnace. There the gas to do the heating had already been burned and was simply hot waste gas. The waste gases of the blast furnace, on the other hand, are not particularly hot, but are highly combustible, and in order to provide a gas burner and combustion chamber these fire brick stoves required, therefore, four connections. First an opening for the gas burner, second an opening to the draft stack, third a connection for the cold blast from the blowing engine, fourth a connection for the hot blast to pass to the tuyères of the furnace.

All of these openings were required to be alternately closed air-tight and opened at frequent intervals, and must retain their tightness under conditions of temperature injurious to any metal available for construction. This meant that all metal parts around these openings had very largely to be water-cooled. The brick stove, therefore, brought many annoyances and difficulties of operation in its train, and, while it gives blast temperatures about 50 per cent higher than those permitted with the iron pipe stove, its first cost is greater, and this with the inconveniences and difficulties of operation and maintenance resulting from the conditions described above, retarded its development somewhat, so that a few plants have continued to use the iron pipe stove, but except in charcoal practice they rapidly disappear.

With this general view of the situation we may proceed to describe the two classes of stoves.

### The Iron Pipe Stove

This stove had a development of about a half century before it was cut off by the preponderating advantages of the brick stove, and in this interval a type of construction was evolved which was almost universally used. This consisted of a large brick chamber lined with fire brick, beneath the brick floor of which passed horizontal pipes with nozzles or connections on their top surface, and a vertical partition in their central plane. On these were arranged U-shaped pipes reaching practically to the top of the chamber, through which the air had to pass on its way from the blowing engine to the furnace; short-circuiting of the U-pipes was prevented by the central vertical partition. Around these pipes burned the furnace gas entering at one end and passing through the rows of pipes and through the baffle walls to the other end, where at last it passed out of the stack.

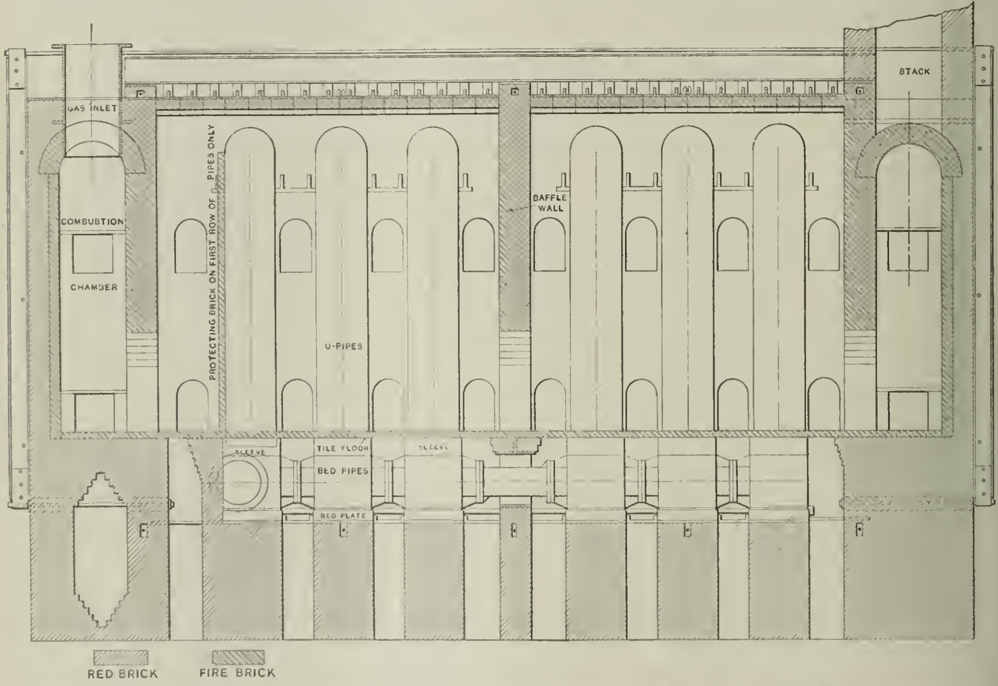

FIG. 1—IRON PIPE STOVE, GLENDON TYPE; LONGITUDINAL SECTION THROUGH CENTER

An excellent design of this type of stove is shown by Figs. 1, 2, 3 and 4, which illustrate a stove built by the Longdale Iron Company at their plant at Longdale, Virginia, under the designs of Mr. H. Firmstone, the president of the company. Fig. 1 is a vertical longitudinal section, Fig. 2 a vertical transverse section, Fig. 3 a sectional plan, Fig. 4 a detail of the U-pipes.

It will be seen that upon a masonry foundation rests a series of cast-iron bed-plates strongly bolted together and planed on their top surfaces. Upon these rest the bed pipes, square in cross section, with a central vertical partition and with three lateral nozzles on each side, in addition to the nozzles for the pipes on top.

None of these bed pipes have any connections on their ends except that the outer chamber of the bed pipe at one end is prolonged into an inlet nozzle, and the outer chamber of the pipe at the opposite end is similarly prolonged into an outlet nozzle. Of course, these end chambers are without the lateral nozzles which connect the chambers to one another. The U-pipes are all of elliptical section in order to get a maximum of heating surface for a given area, and the nozzles on the bed pipes are similarly elliptical in section and of the same size as the end of the U-pipes, these ends being enlarged by a sort of collar cast on them which projects outside the body of the pipe about a half an inch, and which fills the spandrel between the two ellipses to a straight line, this being the shape of the exterior of the nozzles on the bed plates also.

It is perfectly obvious, on account of the central vertical partition in the bed pipes, that there is no passage way for the air except through the U-pipes, and the bed pipes being joined in series, with the U-pipes in parallel, the air passes through an entire set of U-pipes on one bed pipe as a single unit, thence to the next bed pipe, and through all the U-pipes on that simultaneously, and so on.

#### THE JOINTS

The principle of these stoves is obviously very simple, but their construction and maintenance have developed a number of problems. The joints between the U-pipes and the bed pipes are universally sealed with what is known as a rust joint, a mixture of fine iron borings and sal ammoniac made into a stiff paste and caulked into place. This mixture rusts with great rapidity; this converts the whole into an homogeneous mass of iron oxide, which is firmly cemented to the adjacent surfaces of solid metal.

A cast-iron sleeve large enough to go over the nozzles on the bed pipes and the ends of the U-pipes, and about 10 in. in depth, so as to extend 5 in. on each side of the joint when resting on the bed pipe, is slipped over each of these joints and the iron borings run down between it and the surfaces to be sealed. When this is properly done a first-class joint is secured. This is preserved as far as possible from the action of the heat of the direct flame by a floor of flat tile bricks laid between the rows of pipes and resting on the sleeves so as to make a fireproof brick floor above the level of these joints.

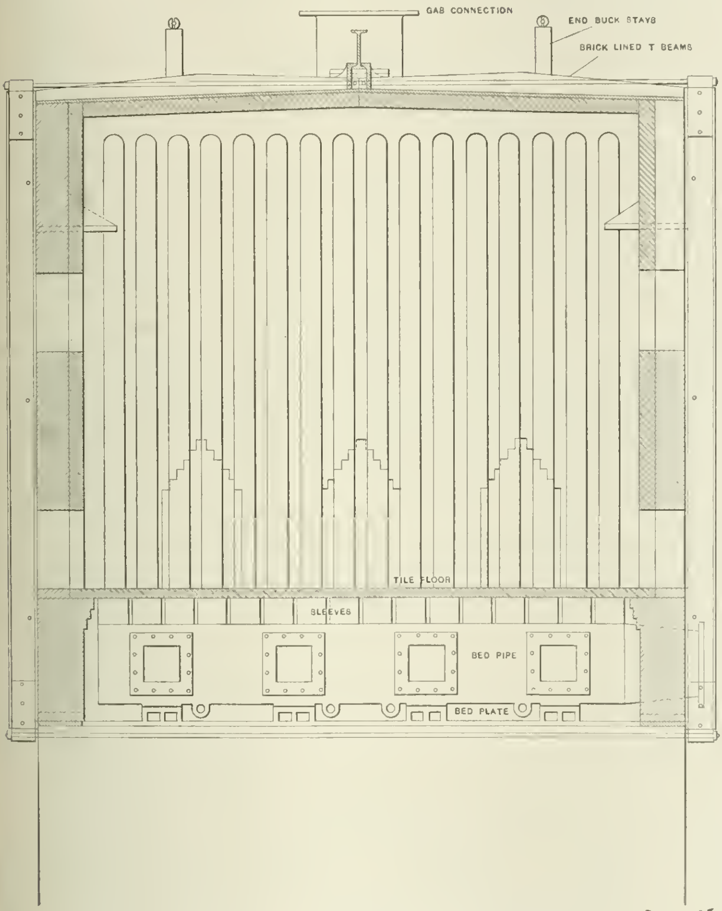

FIG. 2.—IRON PIPE STOVE, GLENDON TYPE; TRANSVERSE SECTION

The U-pipes immediately exposed to the gas coming in from the combustion chamber receive the severest treatment, and these are protected from the direct action of the flame by casting a dove-tail on the side of the pipes placed next to the combustion chamber and sliding over this dove-tail fire brick tiles with a similar dove-tailed slot. These are put on the pipes so as to cover them from top to bottom on the side next to the combustion chamber and greatly increase their life.

### BAFFLE WALLS

In order to prevent the gas from the burners from passing along the top of the stove to the stack without going down around the pipes, baffle walls are built as shown, with openings through their bases through which all the gas has to pass. This forces the gas current to the bottom twice in its course to the stove and secures a good distribution of the flame over the surface of the pipes.

### THE ROOF OF THE STOVE

Many stoves have been built with arched roofs, but these are a great inconvenience when U-pipes have to be taken out and new ones put in, as unfortunately happens not infrequently with this type of stove; and to tear out a portion of this fire-brick arch every time this requires to be done, would add considerably to the expense and delay caused by the operation.

The Longdale stoves were, therefore, covered by long cast-iron T-beams whose lower surfaces were of jaw-shaped or dove-tailed section. These were lined with tiles or shaped fire bricks, the upper part of which fitted into this jaw-shaped section, while the lower part projected out a little beyond the edges of the T-beam. These "shapes" were slid in from the end of the groove and laid in fire clay to make a tight joint and to hold them in place.

In small stoves one end of this T-beam rests on one wall of the oven and the other on the other, but in a large stove, such as that shown here, the span would have been too long for necessary strength, for convenience in handling, and for cheapness in casting the beams, therefore a steel I-beam runs down the center of the oven above the T-beams, and these were cast in two pieces, with the joint in the center, the end at the joint having a hook which rests on the lower flange of the I-beam. This excellent construction gives strength and complete protection of the iron work of the roof from the flame, together with convenience and accessibility. Moreover, this construction makes a level top for the stove, convenient to work upon. This latter is important because when changing pipes shear poles of relatively short and convenient length are set up on top of the ovens resting upon the T-beams, and by this means can be placed exactly where desired, which could not possibly be done with an arched roof. By the use of this construction, where a U-pipe requires to be replaced the half-length T-beams immediately above it can be removed to make room for the operation and then restored to place after it was completed with a minimum of labor and time and without requiring work by masons.

### THE SHAPE OF THE PIPES

The elliptical shape of the pipes is due to a desire to obtain maximum surface for a given area, which may seem at first sight unnecessary, because it might be thought that the area was unobjectionable and that it would be simpler to make the pipes round and not bother about the increased area.

This, however, is open to two objections. First, the length of the bed pipe required for a given number of U-pipes would be greatly increased, which would be objectionable from every point of view, and second, velocity is a matter of much importance in securing proper transfer of heat, much greater transfer being effected at high velocities than at low. Therefore, by constricting the area the velocity of the air passing through the pipes is increased and the temperature obtainable with a given amount of heating surface thereby increased also.

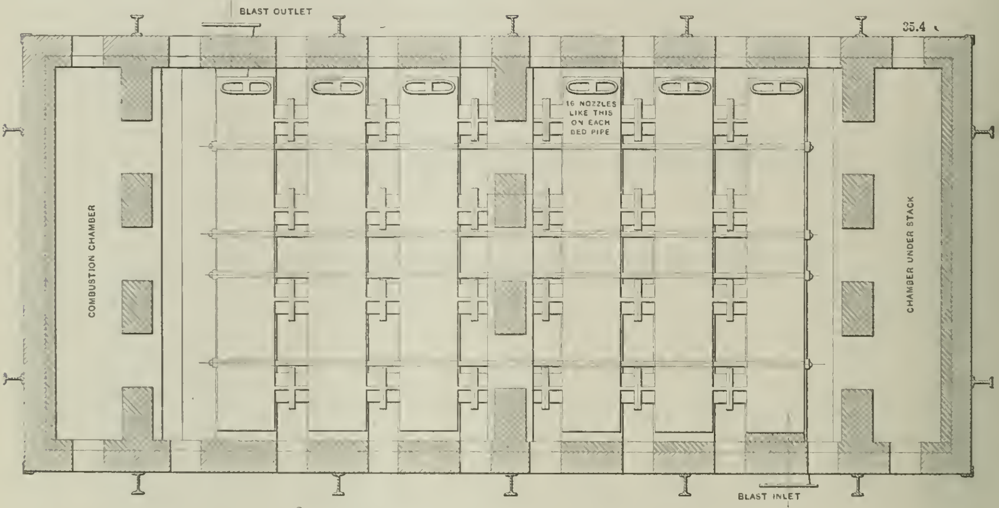

FIG. 3—IRON PIPE STOVE, GLENDON TYPE; SECTIONAL PLAN

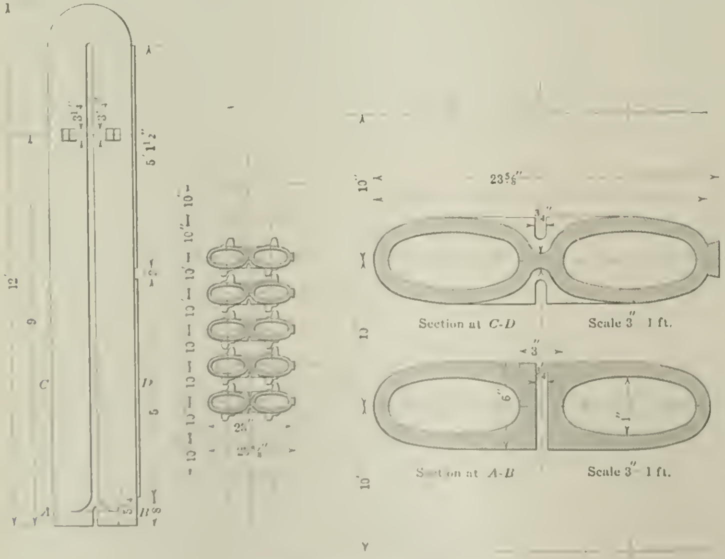

FIG. 4—HEATING PIPES

Many stoves have been built with round pipes, and at the end next to the combustion chamber this is probably wise, because the relatively narrow cross-section of the elliptical pipes makes them bend about much worse under the influence of the flame than do circular pipes whose diameter is equal to the major diameter of the elliptical pipe. But in the rows which are further from the combustion chamber this does not hold to anything like the same extent, and there is probably ample justification for the use of the elliptical section in those rows.

### TWO TYPES OF IRON-PIPE STOVES

Stoves of this general type are divided into two classes, known respectively as the "Glendon" and "Durham," from the former well-known works in the Lehigh Valley, which used and advocated the two types.

There is no essential difference in the construction of these two types, the only difference being in the directions in which the flame and air pass through them. The Glendon stove, as illustrated by the drawings, Figs. 1-4, is on the countercurrent principle. The cold air enters at the draft stack end of the stove and progresses through increasing temperatures to the combustion chamber end, where it is discharged, while in the Durham stove the opposite procedure is followed. This latter at first sight is amazing and contrary to reason, but it appears to be an established fact that higher blast heats can be obtained from stoves of this kind than can be obtained from the Glendon type. The latter type is definitely limited, if it is to give long life and low repair cost, to 850 deg. Fahr., while from 900 to 1000 deg. may be obtained in the Durham type of stove. This is for the reason that when the counter-current principle is used the pipes next to the combustion chamber carry air already heated up almost to the limit of temperature for the stove, and are exposed on the outside to the flame directly from the combustion chamber. They are, therefore, not cooled off or protected on either side, and if very moderate temperatures be exceeded they will fail in one way or another under this combined assault from within and from without.

In the Durham stove, on the other hand, the coldest air passes immediately into the hottest pipes and cools them down to such a degree that they can withstand the external heat. Of course, in this type of stove the waste gases must pass off at a temperature at least 200 or 300 deg. higher than that of the hot blast they are discharging, otherwise the last rows of pipes would be worthless and would absorb no heat, while in the Glendon type of stove the hot gas may be discharged at a temperature several hundred degrees lower than this and still impart heat to the cold blast just entering.

I do not know of a single case in which any investigation has ever been made of the thermal efficiency of iron-pipe stoves, but I am convinced that that of the Glendon type is considerably higher than that of the Durham. On the other hand, if there be no use for the gas saved by this superior stove economy, as was generally the case at plants where these stoves were in service, then it is much better to burn this gas even though the economy of the operation be low, and convert its heat into increased blast temperature which exercises a beneficial effect upon the fuel economy of the plant as a whole.

## Fire-Brick Stoves

The early stoves of this type were of large diameter in comparison with their height, and contained four passes, each passage of the gas vertically through the stove being called a pass. Following the original Whitwell patent a vast number of modifications sprung up and the shape of the stove has undergone an alteration which has now given it a height of four or five times its diameter.

The number of passes has been the subject of experiment, as has almost everything else connected with the stove. It was gradually realized that the fourth pass frequently contributed very little to the heat of the blast, and as every additional pass meant giving up valuable space in the stove for partition walls, with added complexities of brick work at the top and bottom to form safe and durable passageways from one pass to another, the number of passes was reduced to three, to two, and finally to one. Stoves of this type were brought out by Mr. Hugh Kennedy some thirty years ago, which had a single pass straight through from the bottom to short chimneys on the top.

This did away with the necessity of building a chimney, for the stoves had simplified the brick work to the last degree, but the results in practice were unsatisfactory and the stoves did not give the heat desired. They have, therefore, practically passed out of use, and as a result of this and of the gradual disappearance of the four-pass type almost all the stoves built in recent years have been either of the two-pass or the three-pass variety.

## The Three-Pass Central Combustion Chamber Stove

The reason for three-pass stoves is that an odd number of passes brings the gas to be discharged at the top of the stove and by adding a relatively short stack immediately on its top we can obtain the draft necessary without the inconvenience of returning the gas back to the ground level and providing a separate stack for it.

The central combustion chamber is for the reason that, as the average temperature of the brick work is higher around the combustion chamber than elsewhere, it is likely to expand to a greater extent there than anywhere else. When the combustion chamber is in the center this excess expansion takes place along the central axis of the stove with complete symmetry in all directions, while the fact that the annular wall which constitutes the outside of the combustion chamber and presumably attains the highest temperature does not support anything at the top, makes it perfectly free to expand and contract without the destruction of any part of the stove. It is claimed in behalf of the central combustion chamber stove that the side combustion chamber locates this unequal expansion unsymmetrically in the stove with a tendency to greater stresses on one side than on the other.

Moreover, the last pass is very much lower in average temperature than the combustion chamber, and in the McClure stove this relatively cool pass extends all around the outside of the stove and tends to cut down the radiation losses below what they are when the combustion chamber is just within the stove wall on one side.

### THE M'CLURE STOVE

These two ideas underly the design of the McClure stove, which is one of the best-known types of 3-pass stoves, built by the George W. McClure & Sons Co. This is shown in sectional elevation by Fig. 5, the horizontal section at the level of the hot blast outlet is shown in Fig. 6, a horizontal section of the checker work is shown in Fig. 7. It will be seen from Figs. 5 and 6 that gas and combustion air are introduced at the bottom, pass up through the central combustion chamber, down through the first four rings of checker work to the bottom of the stove, where they pass through arches in its intermediate wall, and so up through the exterior row of checkers to the top, where they pass out through the chimney valve and up the stack. The stove is drawn as "on blast," so the chimney valve is shown shut and the arrows are shown in the reverse direction to that described and illustrate the course of the blast as it passes through the stove and finally out the hot blast opening.

It will be seen that the stove contains two domes, one a spherical one resting on the intermediate wall which separates the second and third passes of the gas and one conical one which lines the conical steel dome of the stove structure and prevents its destruction by heat. Fig. 8 shows a perspective view in section of the lower portion of this stove.

The cold blast valve is a flat bell valve rising against a seat bolted into the top of the stove and renewable through the door in the stack in case of necessity. The cold blast elbow directs the air up against the under side of this valve in order to keep it cool and by this means dispenses with water-cooling for it.

Cleaning doors for the space outside the spherical dome are provided just below the top of the cylindrical portion of the stove, while cleaning doors for the portion inside the stove dome are a short distance below these and give access to doorways through the intermediate wall which are bricked up when the stove is in operation but which may be opened to allow passage into the stove for cleaning.

Clean-out doors are also provided at the base of the stove, opposite the arches which furnish communication between the second and third gas passes.

### THE ROBERTS THREE-PASS STOVE

This stove, the design of Messrs. Frank C. Roberts & Co. of Philadelphia, and shown by Figs. 9, 10, 11, 11a and

12, also uses the central combustion chamber principle, but instead of having the second and third passes annular, the space outside the combustion chamber is divided into eight sections by two pairs of parallel walls at right angles to one another whose distance apart is about the same as the diameter of the combustion chamber. This makes four square spaces at the opposite ends of the two principal axes of the stove, and four triangular spaces between these, as shown by Fig. 12.

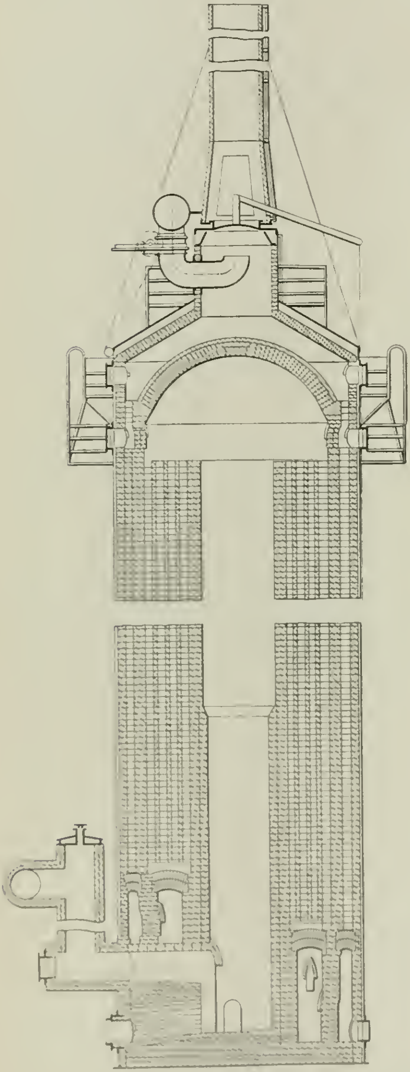

FIG 5

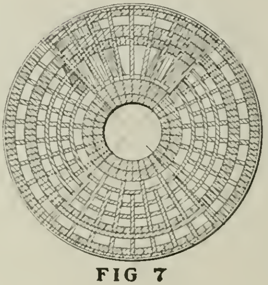

FIG 7

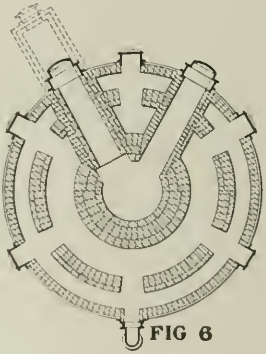

FIG 6

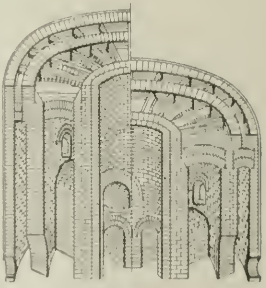

FIG 8

FIGS. 5 TO 8—M'CLURE THREE-PASS STOVE

The intermediate dome of the stove, instead of being a segment of a sphere, is cross-shaped in plan, the tops of the two crosses being arched over with intersecting arches. The gases of combustion pass up through the central combustion chamber, then down through the four square areas within and under this cross-shaped intermediate dome, to the bottom, then up again through the triangular areas, and so to the stack.

The stove, instead of being built of circle bricks and straight bricks laid on the flat, as is the case with the McClure stove, is built up of tiles set on edge and interlocking with one another, as shown by the isometric view, Fig. 12. The checkers are square, instead of having radial ends and circular sides, as in the McClure stove.

This design is used so as to control the gas current to some extent and prevent its traveling too much on one side or another, as it has sometimes been claimed to do in the case of the annular passages of the McClure stove. The cold blast valve and inlet pipe are necessarily located at the top and the current of air is directed against the chimney valve to keep it cooled as in the McClure style.

### Two-Pass Stoves

Commonly two-pass stoves have shared the pre-eminence with three-pass stoves in the best modern practice. In the case of the two-pass stove the valves are all at the ground level, so that any blast leakage has at least a fair chance of being detected by the sound it makes, and the interior construction of the stoves is the simplest possible.

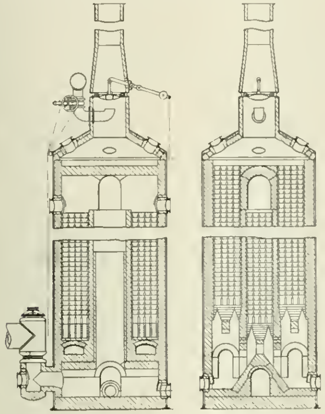
Only a single brick dome is required, and therefore the gas in passing from the combustion chamber to the checkers has only to pass over the top of the combustion chamber wall and down. At the bottom the arrangement of flues for gathering burnt gases from the checker work and leading them to the chimney valve, and distributing the blast from the cold blast valve to the checkers is also extremely simple. Moreover, no space is given up to any intermediate wall of any kind.

### TWO-PASS SIDE COMBUSTION CHAMBER STOVES

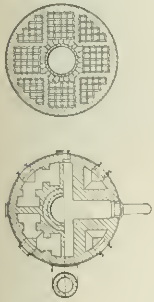
Some operators claim that, while the central-combustion chamber is theoretically correct, in practice the side-combustion chamber type gives little or no trouble if properly constructed, and, owing to the fact that the side-combustion chamber is immediately adjacent to the gas and clean-out openings, it is easier to keep clean than is the central combustion chamber because of the distance of the latter from the operator, and the consequent necessity of removing the accumulation of dirt and slag in the center of the stove at a distance of 8 to 12 ft. from the closest point which the operator can reach. Moreover, the tendency of the blast to wander in the checker work of the two-pass central-combustion type of stove seems to be established beyond question, which is a serious drawback to its efficiency.

The cross-section of the checkers for a stove of this type of a given size is almost twice as great as that of the checkers of the second and third passes in the McClure stove, and this excess area causes a very low velocity through the checkers, so that a very small difference in draft on one side or another will cause a difference in the flow on that side.

The chimney is necessarily at one side in this type of stove and the gas passing through the checkers nearest it has the shortest path to the stock, and for that reason the greatest flow will generally take place on that side, with corresponding inactivity in some other region, whose usefulness is thereby greatly reduced. This is for a reason which must never be forgotten in matters of heat conductivity to or from a fluid, particularly a gas, that high velocity of the fluid absorbing or emitting the heat is of the same order of importance as temperature-difference and surface.



FIGS. 9 AND 10—ROBERTS 3-PASS STOVE



FIGS. 11 AND 12 —ROBERTS 3-PASS STOVE

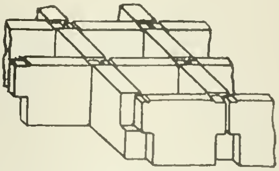


FIG. 11A—ROBERTS 3-PASS STOVE

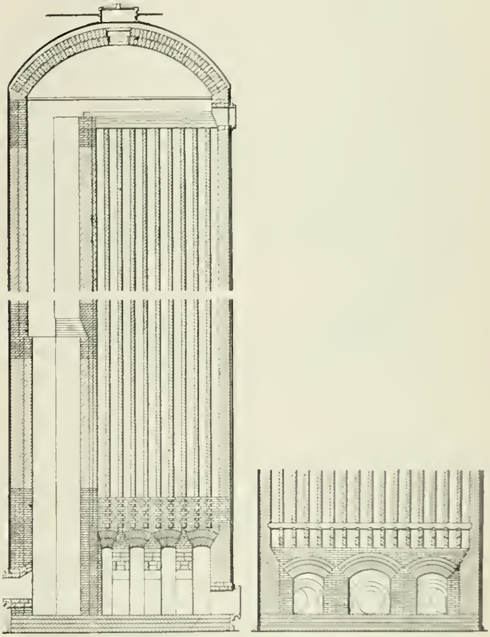
Efforts have been made to overcome this tendency by equipping each stove with two or even three chimney valves, but while this is undoubtedly good practice, and while two such valves are becoming recognized as correct practice, even for the side combustion stove, it does not, in the experience of some skilled operators, overcome the difficulty completely. Some recent work done in Germany makes it appear possible that we have neglected this question of velocity in the passes far more than its importance warrants and that our stove practice may be materially improved by paying more attention to it.

For these reasons some operators and engineers prefer the two-pass side-combustion chamber stove.

### THE NELSON TWO-PASS STOVE

This stove is built by Arthur G. McKee, contracting engineer, Cleveland, Ohio. The principal claims for the stove are that it secures a very large area of heating surface in proportion to the total cross section of the stove, and that there is a very small percentage of any brick in it, except standard shapes regularly kept in stock by brick manufacturers.



FIGS. 13 AND 14—M'KEE NELSON STOVE

This stove is clearly shown by Figs. 13, 14 and 15. It will be noticed that the back or inside wall of the combustion chamber is given a radius of a curvature the same as that of the front wall. This is a matter of much importance because when this wall has too flat a curvature it becomes a very weak arch and does not resist the thrust due to the expansion of the checker work, and in the past, before experience had taught this costly lesson, many stoves were put out of commission and required to be relined long before they would have been had this point been properly guarded.

The checkers are square in shape and well bonded. and the walls between the flues on which the checkers are built are substantial, so that while these stoves have only been in use for some four or five years, they are well regarded and have given good service.

### ROBERTS TWO-PASS SIDE-COMBUSTION-CHAMBER STOVE

In order to meet the views of those who desired a stove of this type Roberts & Co. also furnish one of the design shown by Figs. 16 and 17. This stove uses exactly the same checkers as the Roberts three-pass stove. It is so completely shown by the drawings that no fuller description is necessary.

### THE TWO-PASS CENTRAL-COMBUSTION-CHAMBER STOVE

Some operators, while admitting the disadvantage of the three-pass construction and preferring the two-pass type, consider the central-combustion chamber the best, and a type of stove designed by Frank C. Roberts & Co. to meet this demand is shown by Figs. 18 and 19.

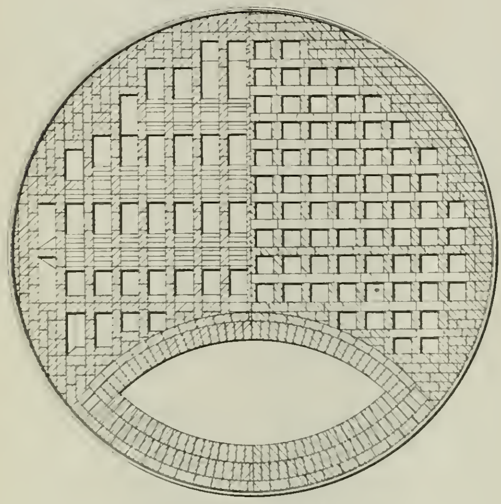


FIG. 15—M'KEE NELSON STOVE

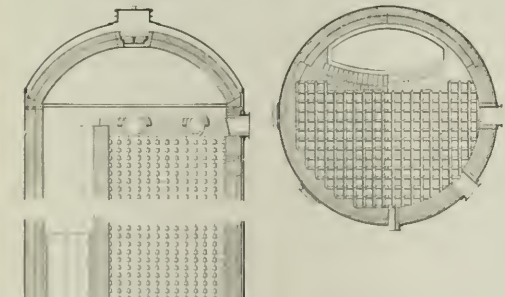
The type of checker work used in these stoves is of the same type as that used in the three-pass stove, except that, instead of being designed for square checkers, it is designed for radial bricks on two sides and circumferential ones on the other sides. This checker work is shown in perspective view by Fig. 19. The construction of the stove is obvious from the drawings and from what has been said of the principles on which it is based. It is provided with the ordinary accessories in the way of cleaning doors, etc.



FIGS. 16 AND 17 ROBERTS TWO-PASS SIDE COMBUSTION STOVE

Mr. Julian Kennedy was one of the first designers of two-pass central-combustion-chamber stoves and used instead of brick checkers hollow key tiles with openings about 9 in. square through the center. The sides of these were radial and the fronts and backs circumferential, so that when stacked up in the stove they made a series of radial checkers of gradually increasing circumferential width passing from the combustion chamber back to the lining of the stove.

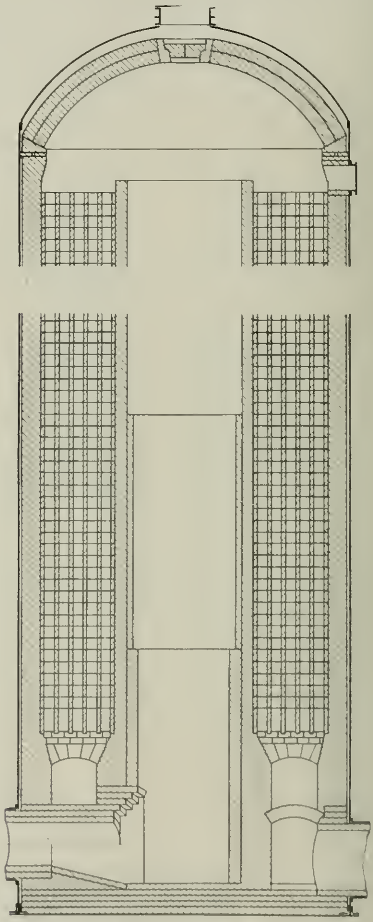


FIG. 18—ROBERTS TWO-PASS CENTER COMBUSTION STOVE

The objection to this construction was that a special shape of hollow tile was needed for each ring of checkers and that the partition wall between each two checker openings being made up by the adjacent sides of two of these hollow tiles was split vertically, therefore its strength was not great, and if one of these gave way it was likely to turn over and obstruct the checker completely. If this happened anywhere in the checker except right at the top it was practically impossible to fix it, and that checker was lost to the stove for the balance of the life of its lining, so such stoves now generally have checkers of brick work built up in the ordinary way.

### Stove Values and Fittings

#### HOT BLAST VALVES

One of the most important details connected with stoves is their hot blast valves. Long experience with these has now developed a type which is in almost universal use on all stoves, subject, of course, to individual variation in the details. This consists of a mushroom or a poppet valve resting on a water-cooled seat, the valve being supported by a water-cooled stem. The design used by the McClure Co. is shown by Figs. 22 and 23.

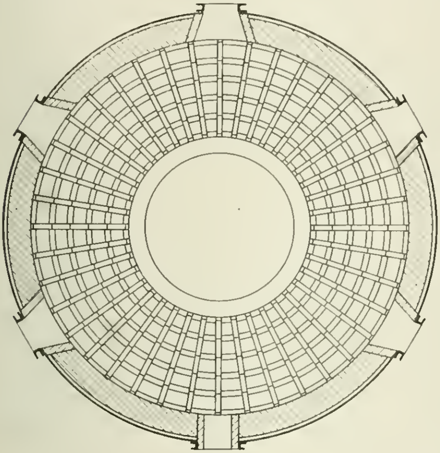

FIG. 19—ROBERTS TWO-PASS CENTER-COMBUSTION STOVE

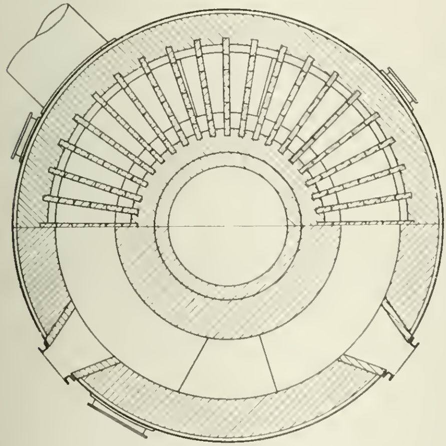

FIG. 20—ROBERTS TWO-PASS CENTER-COMBUSTION STOVE

Commonly the valve is water-cooled as well as the stem, but in the McClure type of hot blast valve this is not done, the valves are made solid without water cooling. The reason for this practice is that if water-cooled valves leak they may discharge a great quantity of water into the hot blast by which it is at once absorbed without showing the least sign, but the effect of this moisture is highly detrimental to the furnace. Moreover, it is claimed by some experienced furnace-men that hot blast valves last about as long without water cooling as they do with it, and that it is better to dispense entirely with the danger of leakage even at the price of a somewhat shorter life of the valves.

The stem, of course, must be water cooled because it must pass through a gland which is required to make a tight joint on it in all positions. This would be quite impossible with the stem heated to redness as it would be if the valve had been for two hours in the closed position. It was formerly the custom to mount the gland immediately on top of the dome-shaped cap of the hot blast valve, but more recently the practice has prevailed of putting in a long sleeve, in the present case about 6 ft. long, which is simply a loose working fit on the valve stem and carries the gland on its top.

The air cooling on the outside of this sleeve prevents the stem from ever getting very warm and the length of the sleeve is such that the portion of the rod which goes inside the hot blast valve proper when it is closed does not come anywhere near the gland when raised into its highest position. This has brought about a great improvement in the conditions of operating and maintaining hot blast valves. It will be seen also that a two-inch air connection is provided at the base of this sleeve whereby additional cooling effect may be secured if desired.

The hot blast valve body is covered with a cast steel cap as shown, and this top is provided with a flange which makes a water box of its upper surface, and the water discharged into this, after cooling the stem, keeps it in good shape. This is, however, protected by an inside cast-steel cover resting on the brick lining of the hot blast pipe. In many cases this cast steel cover is replaced by two large semicircular fire-brick tiles with a hole cut out in their center large enough for the valve stem to pass through, these semicircular tiles resting on the brick work of the lining exactly as shown for the cast cover.

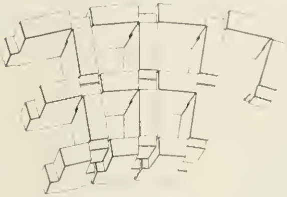

FIG. 21—ISOMETRIC VIEW OF CHECKERS

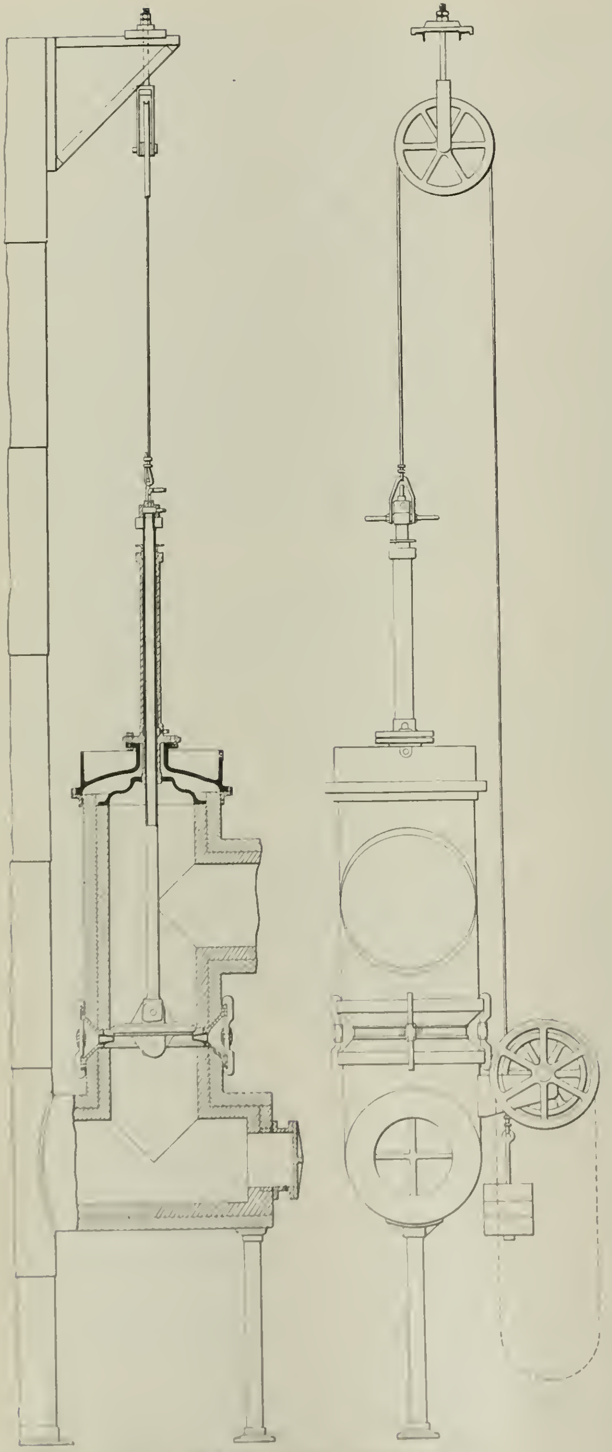
The water-cooled seat is generally made of bronze, cast hollow to provide for a rapid circulation of water through it. In some cases cast-iron seats with a coil of water pipe cast in them are used, but in good modern practice the bronze seats are becoming almost universal.

It will be seen that the hot-blast valve body is cut entirely in two by this seat and held together by clamp bolts which draw together the top and bottom portions of the valve body so as to make a joint on the top and bottom of the valve seat. This arrangement is used in order to facilitate the changing of these seats, which owing to the high temperature and the abrasive action of flue-dust to which they are exposed are subject to heavy wear and must be renewed quickly, since the blast must be off, and the whole furnace stopped in order to make the change. By slacking off the right and left hand nuts of the clamp bolts and screwing them out until the flat faces on the end of the straight portion of their shanks engage with the flat faces on the seat-rings the latter may be forced apart by an amount slightly greater than the vertical height of the shoulder around the valve seat, and the latter can then be slipped out and a new one quickly inserted. When this is properly centered and the hot blast valve body drawn back to



FIGS. 22 AND 23—M'CLURE HOT BLAST VALVE

place, the projecting ring or shoulder around the seat of the upper flange holds it securely in place.

The hot blast valve is suspended from a rope which passes over a high pulley and back to a drum mounted in bearings bracketed to the side of the hot-blast valve casing. The rope is given two or three wraps around the drum and a counterweight equal to the hot blast valve and stem is attached to the lower end. A hand-wheel on the drum is provided and with this arrangement the stove tender can raise and lower this valve without difficulty. In order to facilitate changing hot blast valves, when this becomes necessary, the high pulley is now, in some cases placed at the top of the stove. This gives ample height to raise the valve, not only to open it, but to lift it clear out of the valve chamber. The high suspension also facilitates swinging the valve to one side in order to lower it to the ground. These are details of much importance when valves have to be changed, since they facilitate doing it quickly. For the same reason the bolts used to bolt the outside cap to the hot blast valve casing should be key bolts, or else the bolt holes should be slotted, so that as soon as the bolt is loosened it may be removed without unscrewing the nut all the way.

### THE COLD BLAST VALVE

A standard design for this valve has gradually been evolved, and while the individual valves used by different stove builders differ in details, the general principle of all is the same. They are all flat slide-valves designed to withstand pressure from one direction only, since this is all that is necessary for this service and are always operated by a handwheel and pinion.

Figs. 24 and 25 show the design of the cold blast valve used by Frank C. Roberts & Co. Its construction and operation are obvious from the drawings. There is one point, however, which might escape the casual observer and is therefore worthy of mention. The rack on which the pinion works to operate the valve is not rigidly attached to the latter, but is free to slide between the guides shown in Fig. 25 within the limits set by the stops which come against these guides and through them move the valve proper. The end of the rack is widened out to a T-shape and this covers a slot through the main valve. When the valve is to be opened to put the stove on blast the unbalanced pressure on it is very great, and if the stove tender succeeded in opening it in spite of the friction produced by this pressure, the rush of air into the stove might be so rapid as to do damage. With the arrangement shown the first movement of the pinion slides the rack proper on the back of the main valve and thus uncovers the port in the latter; through this the air flows until in about a minute the pressure within the stove is the same as that in the blast main; this relieves the friction on the valve, which can then be moved back into the valve housing without further difficulty.

### STOVE BURNERS

Only one type of stove burner is in extensive use, known from its first inventor as the Spearman burner. An excellent design of this by the Wm. B. Pollock Co. of Youngstown is shown by Fig. 33. The gooseneck rests on a slide supported on a hollow base which serves as a gas inlet. When the gooseneck is in the position shown, the opening in its base corresponds with that in the slide and its end projects inside the burner opening in the stove so that the gas enters and burns with the air which is drawn in around the gooseneck and also through the small pipe in the center. The purpose of the latter is to give more intimate mixture of air and gas, thus giving better combustion.

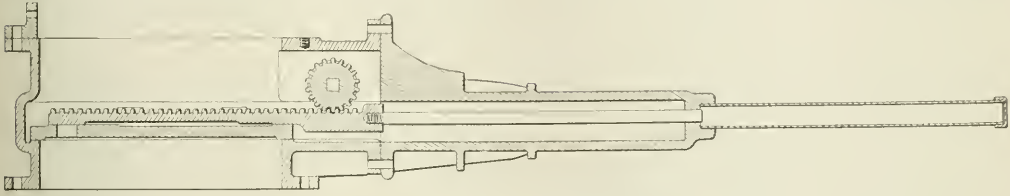


FIG. 24—ROBERTS COLD BLAST VALVE

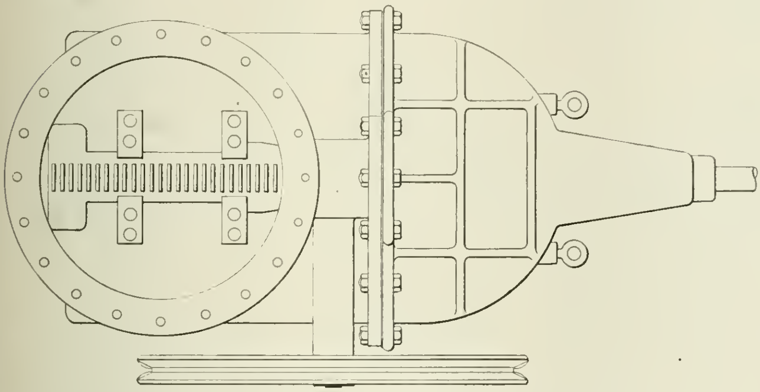

FIG. 25—ROBERTS COLD BLAST VALVE

When the gooseneck is withdrawn its slide closes the opening in the base and the opening in the stove is closed by a cap or door in exactly the same way as the chimney valve opening is closed in the Stenbakken design. (See Fig. 32 on p. 407.)

Much attention is being paid to stove burners at the present time with a view to securing more perfect combustion by better mixture of the air and gas. Mr. A. J. Boynton, superintendent of the Lorain furnaces of the U. S. Steel Corporation, has put in use an excellent burner which is a decided departure from standard practice. The burner consists of a square casting with a round projecting nose which fits close against the seat ring in the burner opening. This casting is mounted on small wheels so that it can easily be withdrawn to permit closing the burner opening in the regular way. The gas enters at the rear and passes through a number of flat passages cored through the casting. The spaces between these passage ways are about the same size as the passages and open at the sides, these multiple side openings being under the control of a slide on each side so operated as to give the same opening at each air port and to vary the amount from nothing to full opening.

The gas is controlled by an independent bell valve in the supply pipe. This gives complete independent control of both air and gas supply and intimate mixture of air and gas at the nose of the burner.

### CHIMNEY VALVES

One of the earliest forms of chimney valves is of the same form as the cold blast valve, but very much larger and water-cooled to withstand the action of the hot chimney gases; its seat is also water-cooled. Such a valve designed by Roberts & Co. is shown by Figs. 26 and 27. Its construction is so clearly shown by the cuts as not to need much description.

Like the hot blast valve this valve is counterweighted and operated by a hand-wheel and drum around which the suspension rope passes. The side furthest removed from the stove is turned to a joint on the face and the pressure of the blast when the stove is on blast holds the valve to its seat. When the stove is blown off it then swings comparatively freely and can be raised by the operator without much difficulty.

A mushroom valve of the same type as that used for hot blast has also been largely used in the past. A type of this valve designed by Frank C. Roberts & Co. is shown by Figs. 28 and 29. This also is water-cooled and operated exactly like the hot blast valve.

Valves of these two types, however, have proven very large and unwieldly and rather troublesome in operation, and there has been a strong tendency in the last few years to develop a type of valve which was more accessible, could be more easily operated, and which did not require water-cooling. One of the first and most successful of these was the Kennedy-Morrison valve shown by Fig. 30. This valve is exactly on the principle of the Spearman burner except that it makes as close a joint as possible against the reinforcing ring around the chimney opening in the stove, so as to prevent the ingress of any outside air to the flue. When the elbow which carries the burnt gas from the stove to the underground flue is withdrawn its slide seals the flue opening exactly as in the Spearman burner, and the opening in the stove is sealed by a cap held to place by one or more screws mounted in swinging yokes, these screws forcing in the ends of a cross-bar or "spider" pivoted to the center of the cap. (See Fig. 31 on p. 407.)

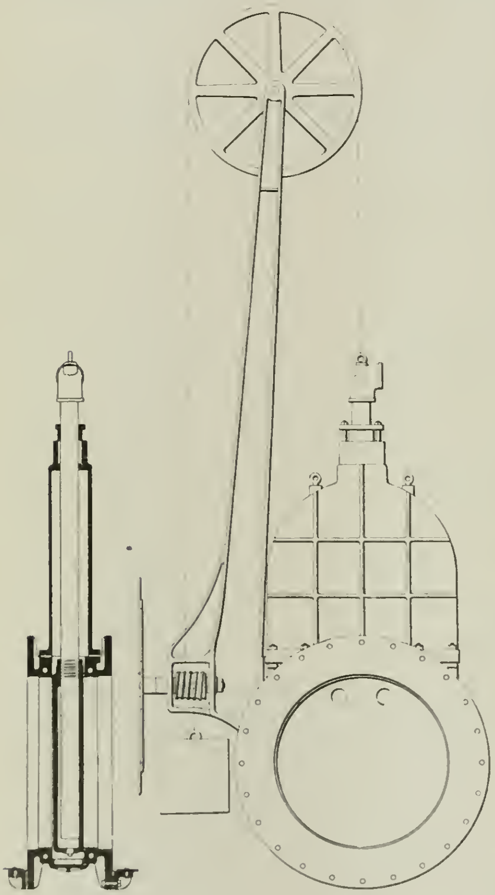

FIG. 27 FIG. 26

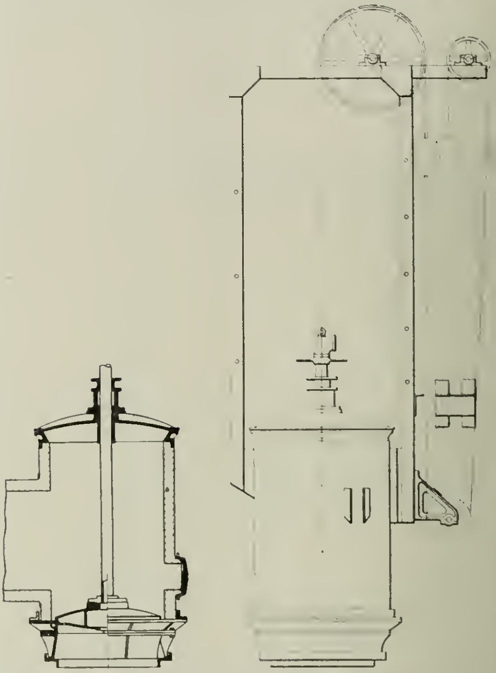
ROBERTS SLIDE CHIMNEY VALVE

The Inland Steel Company have in use a modification of this valve designed by their chief engineer, Mr. Ole Stenbakken, in which the goose neck instead of the sliding back and forth rests on a circular seat, the center of the circle being set off from the central plane of the goose neck proper so that when the goose neck is revolved around this base it is withdrawn from the stove, the opening is then closed by a cap as in the Kennedy-Morrison burner. The construction is shown by Figs. 31 and 32. As these goose necks are very large and heavy it is desirable to reduce the amount of movement and effort required to operate them to a minimum and this is admirably accomplished by the rotation of the goose neck around a vertical axis, its opening, when removed from the stove, is closed by a light steel door.

The chimney valves which are used on the three-pass type of stoves have been shown in conjunction with those stoves and do not need further comment here.

BLOW-OFF VALVES



FIGS. 28 AND 29—ROBERTS MUSHROOM CHIMNEY VALVE

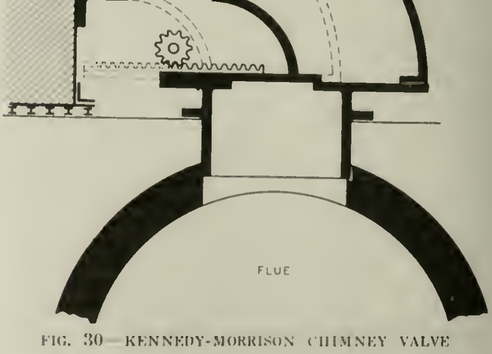


FIG. 30—KENNEDY-MORRISON CHIMNEY VALVE

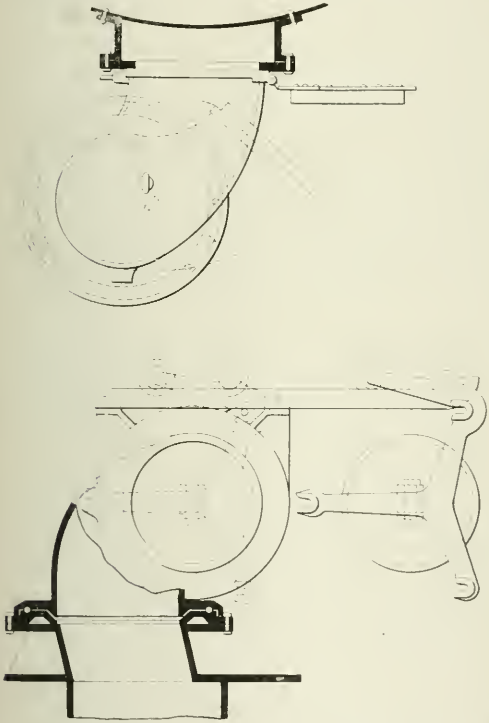
In addition to the valves above described, there is also an air blow-off valve provided, the function of which is to blow off the air left in the stove when it is taken off the furnace, since, of course, the stove must retain the furnace pressure after its outlet valve is closed. This blow-off valve is placed close to the bottom and is sometimes arranged to open quickly with a lever instead of with a screw, so that as violent a current of air as possible will blow out through it and thereby carry as much dirt as it can from the passages around the base of the stove.

The construction of this valve as used in the McClure stove is shown by Fig. 34. It will be seen that the elbow in which the valve is mounted is arranged to swing as a whole so that this opening serves as a cleaning door as well as a blow-off.

### STOVE CASTINGS

In former times the reinforcing rings around doors, valves, burner openings, etc., were made of cast iron, but the liability of cast iron to crack when subjected to expansion and contraction stresses, and the enormous difficulty of getting at the rivets holding these to place after the stoves are bricked up has brought about the adoption of steel castings for these fittings in all good modern practice. These are somewhat more expensive in first cost, but the failure of a single cast iron fitting after the stove was in operation would involve a loss several times greater than the whole difference in cost between cast iron and steel fittings.



FIGS. 31 AND 32—STENBAKKEN CHIMNEY VALVE

### PACKING

It is almost unnecessary to remark that as the steel shell of the stove is exposed to the air and protected by heavy brick work, it remains comparatively cool while the bricks are heated far beyond the red heat. Therefore, the brickwork expands several times more than the shell.

It is also characteristic of brickwork that while it expands when subjected to heat it tends not to contract to the same amount, and therefore is subject to a small but permanent growth. For this reason the shell of a stove must be considerably larger than the outside diameter of the brickwork, and in order to exert a certain amount of pressure against the bricks and keep them to place this space must be filled with some yielding material. Some constructors prefer to use for this purpose pumice-cinder, others clay, and others again a mixture of these materials.

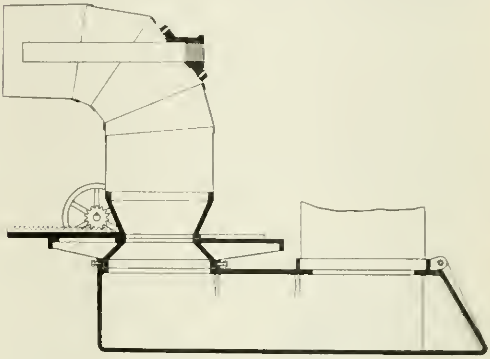


FIG. 33—STOVE BURNER

A similar provision must be made for the vertical expansion of the brickwork and the brick dome of the stove must be left many inches below the shell when the stove is lined. There is not the same necessity for packing material in this space as gravity tends to hold the dome to place, and this space may, therefore, be left open without detriment.

### STACK FOR STOVES

Mechanical draft has never been applied to hot blast stoves so far as I know, their draft always being supplied by a stack.

The three-pass stoves each have their individual stack resting on top of them. In the case of the two-pass stoves the choice of two styles of construction is possible. One is to have a single stack for a battery of three or more stoves, the entire complement of one or two furnaces. The other alternative is to have a single stack for each stove directly connected with it.

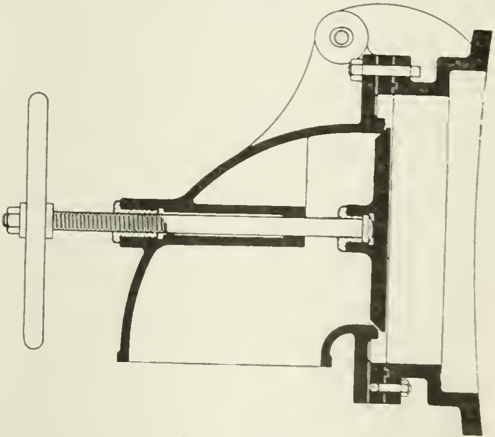

FIG. 34—BLOW-OFF VALVE

The former practice is very much the more general, and in my judgment much to be preferred, since one large stack is undoubtedly cheaper than three or more small ones of the same total capacity. Moreover, if it be desired to cool off one stove for repairs and it be connected only with its own individual stack, no air can be drawn through it after it has cooled off a little, because there is no difference in temperature to produce a draft, although the stove may be far too hot to work in or even to enter. But if all the stoves are connected to a common stack then the chimney valve on the stove which it is desired to cool off may be opened to some extent without seriously impairing the draft of the other stoves and the cold air thus drawn through it will cool it down to a temperature at which it can be entered and repaired in a small fraction of the time in which it would cool to the same extent without this assistance.

### THE DOMES OF STOVES

In the early days many stoves were fitted with a cylindrical top as shown by Fig. 35, and this shape conforms with the mechanical requirement that all sections of the stove shall be circular in order to resist deformation, but this style of top is difficult and expensive to fit and seems particularly liable to give out along the square corners where the horizontal cylindrical surface of the top meets the vertical surface of the stove body, and stoves are now almost universally fitted with either conical or spherical tops.

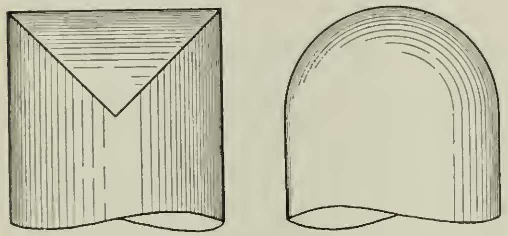

FIG. 35—CYLINDRICAL STOVE TOP

### THE BOTTOM AND BASE RING OF STOVES

The bottom sheet of the stove must of necessity carry all the brickwork in the stove and is, therefore, not capable of repair except by tearing out practically the whole lining of the stove. The principal point of corrosion about stoves appears to be where the cylindrical surface meets the bottom plate, and owing to this corrosion old stoves are liable to fail at this point sooner than almost any other, the base ring contains nearly all the openings made into the stove for cleaning out doors, valves, etc., and its strength is thereby greatly reduced. For these reasons the bottom section should be made of heavier material than the rest of the stove.

The stove base instead of being set down flat on a masonry foundation, as formerly, now generally rests on a set of T-rails placed close together, this carries it up off the ground and prevents corrosion to a large extent.

The joint where the bottom sheet meets the side sheets should always be made with the utmost care and almost without regard to expense. It is very doubtful if flanging is a good construction at this point. A heavy angle bent to the circle and riveted to the bottom and side sheets furnishes a better construction.

### THE CHECKERS IN STOVES

It has been the practice to make checkers in stoves about nine inches square in the past, but this practice is now beginning to undergo a change which is likely to be very rapid, for the reason that until quite recently gas cleaning was not practised to any considerable extent in this country, while the blast furnace gas produced here probably carries more dirt and fine ore than that of any other country, because of the predominant portion of fine sandy ore used.

This dust is carried into the stove by the gas and deposits on the brickwork which, of course, is composed largely of silica; under the intense heat to which this brickwork is exposed the iron ore constituting the larger portion of the flue dirt is fused to the brickwork and the wall of the combustion chamber soon becomes glazed over and finally is slagged away by this action, so much so that a false wall is always built in the combustion chamber, so that this wall may be renewed when it is burnt out without affecting the stove as a whole. In one plant, formerly under my management, we never counted that these walls would last over eight or nine months without repair, and this was due almost entirely to the slagging action of the iron ore carried by the gas.

In the checkers the conditions are not quite so bad, because the temperatures are much lower, but vast quantities of dirt settle on these in light flocculent masses, about the best non-conductor of heat which could be found for such high temperatures. These flocculent masses greatly reduce the flow of gas through the stove and seriously impede the passage of blast through it also. Therefore, it is now necessary at intervals to take each stove off the furnace for several days, cool it down so that it can be entered, put men in the upper dome and clean these checkers by dropping through them weights suspended from a rope or chain. This is a highly laborious performance, and from the nature of the case more or less ineffective. In order to carry out this operation at all, it is necessary to lose the use of the stove for from one to two weeks under the best conditions, and during that time, unless the furnace is more than usually well provided with stove capacity, the blast is improperly heated, and the fuel economy of the furnace suffers.

In recent years it has been found that with the exercise of a certain amount of care the gas can be scrubbed practically free of these impurities at comparatively small expense. This eliminates the necessity of allowing for a coating of flue dust from one to three inches thick on all sides of the checkers. When this is done it becomes a simple matter to use checkers six inches square which are not only as good as, but much better than checkers nine inches square when dirty gas is used.

It is obvious that the amount of heating surface which can be put into a given stove with six-inch checkers is far greater than that which can be put into it with nine-inch checkers and this means that the stove capacity needed to supply a given amount of heat to the blast may be more cheaply obtained, not only in operating cost but also in first cost by putting in a gas-washing plant to supply clean gas, and using somewhat smaller stoves with smaller checkers. The smaller stoves so designed contain more heating surface and maintain a higher efficiency than the larger stoves under the old conditions with dirty gas.

### The Number of Stoves Per Furnace

There is no theoretical reason why one iron-pipe stove should not be sufficient for a furnace, because it is an apparatus which works continuously by the conduction of heat through metal walls exactly as a boiler does. Barring repairs it could run on indefinitely, and small furnaces in the early days were frequently run with only one stove.

As a matter of fact, especially at large furnaces, the number of stoves is increased for two reasons: First, it is difficult to build a single unit large enough to heat the quantity of blast required for a large or even a moderate-size furnace, and at the same time to design it so as to give good control of the heat in all parts. Second, after a certain point is passed it costs no more to build the required stove capacity in two or three units than it does in one, while if there be, say, three stoves on a furnace, then, when one of them requires repairs the other two are still able to heat the blast to a very valuable extent; whereas, if only one stove be provided, when this goes down for repair the furnace must shut down because it is commercially impossible to run a furnace on cold blast.

For these reasons two or three iron-pipe stoves are commonly provided per furnace when that type is used.

In regard to the capacity and efficiency of these, little or nothing is known. As a matter of experience it can be stated that the stove illustrated in Figs. 1, 4 is capable of heating six or eight thousand feet of blast per minute up to 850° F. without such overcrowding as will destroy it too rapidly. In regard to economy and efficiency we have not even the guide of general experience to help us, because there is no way to get at the quantity of gas consumed by one of these stoves without careful experiments on gas flow, etc., which, as far as I know, have never been conducted.

It may be safely stated that the efficiency of the Durham type of stove, that is the parallel-current type, is quite low, because the chimney gases must be discharged at a temperature of twelve hundred or more, and even with theoretically perfect combustion this involves a loss of over 50 per cent. of the heating value of the gas.

Turning now to the fire-brick stove, the conditions are entirely different from what they are in the case of the iron-pipe stove, since it is impossible to get along with less than two of these, one of which is being heated up while the other is giving up its heat to the blast. Furnaces were originally operated with only two stoves of this type, but this condition has long since passed away. Less than three are never contemplated, four is only ordinary good practice, and five have been installed with extremely satisfactory results at some plants.

The reason for the increased number of stoves is twofold. First, to have one in reserve, or at least be in a position to spare one for repairs without crippling the plant; second, because the heating of the blast by this process is an intermittent operation, and therefore the temperature of the blast fluctuates with the condition of the stove. When the stove is first put on it has been heated up to a high temperature, which falls as it gives up its heat and the blast temperature is therefore constantly falling.

When only two stoves are provided these variations are so great as to cause serious irregularities in the work of the furnace. By adding a third stove and burning the gas so as to give them what steel men know as a "soaking heat," their temperature falls much less rapidly while they are on blast. The fact that the relative time on gas is doubled while the time on blast remains the same contributes much to this result. This greatly reduces the irregularities due to the intermittent action of the apparatus.

But, when one stove requires to be taken out of service for repair the furnace is then thrown back onto the two-stove condition. This cuts down the heating surface to two-thirds and reduces the average blast temperature materially as well as making serious irregularities in the temperature curve. Therefore, in order always to have the benefits of three stoves four must be provided; this gives three hours on gas for one on blast, which is a step better than the condition existing when three stoves are used.

Four stoves introduce the possibility of operating along a somewhat different plan, with the object of eliminating inequalities of blast temperature still more. This plan is to blow through two stoves simultaneously, leaving them each on blast one hour, but changing them at alternate half hours. This reduces the time of the stove on gas to one-half the total time, but halves the amount of heat taken out of it at any period. It involves somewhat more work for the stove tender, but practically halves the variations of blast temperature from maximum to minimum.

Here, again, we come to the necessity of occasional repairs necessitating a return to three-stove conditions, and this has caused many operators to consider five stoves a good investment, because then four stoves can always be maintained in operation, even when one is being repaired, and when all five are available each one can be left on gas for three hours and on blast for two hours, with still better results in eliminating irregularities in the blast temperature and maintaining a high average temperature without driving the stove too hard when it is on gas.

It will be seen, then, that the number of firebrick stoves to be supplied per furnace depends to some extent upon natural conditions, which we cannot control, and that if the best results are to be attained under present conditions, not less than four must be supplied. But, since the introduction of clean gas at some plants, it has been found that the stoves do not need to come off during an entire blast for either cleaning or repair, and this fact in addition to the increased economy and greater heating surface attainable as a result of clean gas have a tendency to reduce the number of stoves required, and it may well be doubted if five stoves will in future be installed at plants originally designed to use clean gas. It may be that the number required will fall to three.

### EQUALIZING THE BLAST TEMPERATURE

The proposal has been made by several blast-furnace engineers and operators to apply an equalizer to remove the objectionable peaks from the charts of blast temperature, and several of these apparatus have been built. One of the few in this country was that built by John S. Kennedy and the late John M. Hartmann at the Musconetcong furnace, Stanhope, N. J., which has been most successful in operation.

This apparatus is practically a small stove without combustion chamber or valves filled with very small checker work through which the blast passes on its way from the stoves to the furnace. When the blast is very hot from putting on a fresh stove the excess heat above the average is given up to the checker work in which it remains stored until the temperature of the blast falls below the average, owing to the cooling of the stove, when this stored surplus flows out and makes up the deficiency.

Mr. Kennedy has told me that this apparatus smoothed down the "saw teeth" on the blast temperature charts so that the maximum temperature difference for long periods continuously was less than twenty-five degrees. Without such an apparatus the drop in temperature between putting on and taking off a stove will run from 50 to 150°, depending on the number of stoves and how they are handled.

Another method for obtaining a uniform blast temperature is by the use of a cold-wind mixing valve. This valve is located on the hot blast main into which it opens and is connected with a branch from the cold blast main. By opening this valve cold blast directly from the engine can be admitted into the hot blast main, thus cutting down the temperature of the blast by admitting a considerable quantity of this cold air as a fresh stove is put on the furnace and gradually diminishing this quantity down to nothing, at or near the time when the stove comes off.

By this means the blast temperature may be maintained uniform, but this method is open to two objections: First, that the uniform blast temperature is, in that case, the lowest temperature furnished by the stoves instead of the average, and, second, the equalization depends wholly on the skill and fidelity of the stove tender, and if done properly requires such frequent attention by him as militates against his assisting at other work.

Attempts have been made to provide an automatic control of this valve, which would relieve the stove tender of the duty of regulating it and would give perfect equalization of the blast temperature, but so far as known to me none of the apparatus designed for this purpose are now in regular commercial use.

### The Size and Heating Surface of Stoves

Practice in regard to these matters in the past has been based on general experience and the belief of the furnace man or engineer that stoves of about such a size would be sufficient to supply the hot blast for a given furnace. It is not a rule, but it seems to be according to general practice that the diameter of the stove shall be about the same as the bosh diameter of the furnace, and that its height shall be as a minimum that of the furnace and from that up to twenty or twenty-five per cent. more.

Until recently but little attention was paid to the quantity of heating surface furnished per foot of stove height, but there is evidence that this condition is passing and that within a few years stoves will be bought on their heating surface, practically as boilers are today. This has been impossible except in the most general way in American practice until now, because the hard driving of American furnaces, combined with the enormous percentage of extremely fine ore used at seventy-five per cent of them, has made an exceedingly dirty gas, and this dirt depositing on the checkers in the way already described has reduced the efficiency of the stove in proportion to the extent in which it has been allowed to accumulate, so that stoves kept clean and under good management at one plant are capable of heating a given quantity of blast to a much higher temperature than similar stoves at another plant where they are not properly cleaned.

To a large extent these conditions have been past control and absolutely past all calculation. General experience has, therefore, been practically the only guide. With the introduction of primary cleaning for all the gas, that which goes to the stoves will be in vastly better condition than it is now, the stoves will stay clean for far longer periods and will have not only a higher but a more definite efficiency.

The advantages of smaller checkers already pointed out, which become available under those conditions, will cause competition among stove builders to give the maximum amount of heating surface per stove, and we shall gradually reach the place where the capacity and economy of stoves are as well understood as that of any other apparatus around the place, a condition which certainly does not exist at the present time.

There has been in recent English and American literature little or nothing on the hot blast stove from the operating point of view, but in December, 1912, Mr. A. N. Diehl published before the Engineers' Society of Western Pennsylvania a very valuable paper giving the results of long and careful investigation of the subject, and in October, 1913, in a discussion of the sub-

*Col. No. 11—Over and above that required to oxidize the CO present in the flue gas.
†Col. No. 13—Per stove per hour and based on coke having a calorific value of 12 200 B. T. U. per lb. as received.
‡Col. No 14—Based on four stoves per furnace, or 72 stove hours per day on gas and 24 stove hours per day on blast.
Note: All gas volumes and calorific values are at Standard Conditions, 62 F. and 30 in. Hg.
Above test Numbers correspond to those given in Table No. 1.

ject of gas cleaning before the American Institute of Mining Engineers he contributed additional data on the subject.

His tables I. and II. from the first-mentioned paper are reproduced here and will repay careful study.

With clean gas the efficiency of the stove is raised considerably, according to Mr. Diehl's later figures, from 56 per cent. to 64 per cent. This is not a decrease of 8 per cent, but of 12½ per cent (8 ÷ 64) in the gas consumption of the stove and, what is much more important, it brings with it the possibility of obtaining higher blast temperatures with the given equipment of stoves and by this means reducing the coke consumption of the furnace.

Table I. shows the advantage of having a sufficient amount of heating surface for the given conditions and as the use of clean gas makes permissible the use of smaller checkers and thereby increases the heating surface, it may be said that the effect of clean gas is cumulative in its influence on stove design and operation. The best practice as brought out by Mr. Diehl's paper and its discussion favors the use of not less than four and preferably five square feet of heating surface per cubic foot of blast blown per minute measured by piston displacement. When four stoves are used this would mean from one to one and a quarter square feet of heating surface per stove for each cubic foot of blast blown per minute.

This will obviously vary to some extent with the conditions. When high heats are regularly required, as with the use of lean and refractory ores, more heating surface should be provided than with soft and reducible ores which ordinarily do not need such high heats. On the other hand, when there is no use for the surplus gas it may be better to save in the size of the stoves and burn the gas less economically in them to get the desired heat.

Since this article was written there have appeared accounts of recent experiments in Germany in which the heat imparted to the same was greatly increased by increasing the velocity of the gas through it, first by an air jet in the combustion chamber and in the later experiment by use of a fan to increase the draft. It is claimed that by the use of this system so much heat can be stored in each stove that only two are needed per furnace.

The accounts are too incomplete, and it is too early in the development to say what the final result will be, but with the vast improvement made in the operating conditions of stoves by clean gas there is no doubt that many improvements will follow and that increasing the velocity of the gas and blast through the checkers is one of the best ways to increase the rate of heat transmission.

As the efficiency of stoves increases it is very likely that fans will be used to provide draft for them for the reason that high efficiency can only come with low stack temperatures. Chimneys only provide good draft with fairly high temperatures and with a consequent waste of much heat. Therefore, it seems natural to expect that this conflict of requirements will be solved by the use of a fan whose performance becomes increasingly better as the temperature falls and which gives absolute control of conditions of draft, rate of combustion, etc.

The limit of possibility in reducing stove capacity is set by the amount of heat it is possible to store in a given weight of brickwork with a reasonable increase in its temperature, for if too great a drop in the temperature of the brickwork be necessary more gas is required and this limitation must be carefully considered in any plan for reducing the stove capacity.

Three stoves with clean gas and high gas velocity may easily be better than four without those advantages, but whether it will ever pay to reduce the number of stoves below three may well be doubted until overwhelming proof is offered.

**The Gun-crete Company** has opened its offices in the McCormick Building, Chicago. The firm specializes in cement gun work for engineering, industrial and mining structures, and also introduces the Weber system of workingmen's cottages, which, being constructed by the cement gun process, are fire, water and vermin proof, and can be built at a price almost as low as ordinary frame buildings. Other specialties of the firm are the lining and fireproofing of mining shafts and the lining of coal bunkers, etc. Mr. Carl Weber is the president of the Gun-crete Company.

**The question of pole supply** is one of increasing importance as power lines are extended in the West. A study of the value of different Rocky Mountain woods for poles is the subject of Bulletin 67, U. S. Department of Agriculture.

## Recent Chemical and Metallurgical Patents

### Gold and Silver

**Process for Canadian Silver-Cobalt Ores.**—In a patent granted to Mr. Oscar Dyckerhoff, of Karlsruhe, Germany, the inventor states that "a rational, cheap process, which permits the recovery of all the silver and at least the larger part of the cobalt, nickel and arsenic (from Canadian ores) has hitherto been wanting." He proposes a process of chloridizing, as more nearly fulfilling conditions than does any process now in use. Ordinary chloridizing-roasting is a failure when metallic silver exists in an ore in large proportions. The inventor finds, however, that chloridization of such material is easily effected if clay or ordinary loam be added to the mixture of ore and salt. This combination of materials results in the formation, at a suitable temperature, of sodium silicate and chlorine or hydrochloric acid, which latter attacks the silver. The alumina of the clay absorbs the silver chloride. The reactions will ensue at a lower temperature if iron or other pyrite is added to the roast.

The effect of thus roasting at a temperature not to exceed 600 deg. C., is to convert cobalt and nickel into a form (mainly basic sulphate) soluble in dilute acid formed from the roaster gases in absorption towers. The arsenic exists as sodium arsenate, and the silver as chloride cobalt, nickel and arsenic are extracted by means of weak tower acid, and silver by sodium thiosulphate. Several successive roastings and leachings may be necessary in order to secure high extraction. Cobalt and nickel are recovered by precipitation as sulphides, while arsenic may be obtained by crystallization as sodium arsenate. Silver is precipitated from its solution as sulphide. The inventor gives the results of tests showing extractions of 99 per cent of the silver, 69 per cent of the nickel and cobalt, and 95 per cent of the arsenic. These results were obtained, however, only by four successive roasting and leaching operations. (1,085,675, Feb. 3, 1914.)

**Roasting Precious-Metal Residue from Electrolytic Copper.**—The slime or mud resulting from the electrolysis of copper generally contains gold and silver which are recovered by smelting. In order to remove copper as completely as possible before smelting, the residue should be roasted to render copper soluble in sulphuric acid. Mr. **Rowland T. Wales**, of Chrome, N. J., has patented a form of roasting furnace, specially adapted to the roasting of these residues. The material is first filter-pressed, then granulated and placed in the furnace in shallow trays. The roast is given at a temperature of 600 deg. F. The use of trays avoids stirring of the charge, with consequent loss of dust, and permits each portion to be roasted according to its needs. (1,085,831, Feb. 3, 1914.)

### Lead, Copper, Nickel and Tin.

**Making White Lead.**—Roasting apparatus for producing white lead directly from lead ores has been patented by Mr. **Robert A. Stewart**, of Los Angeles, Cal. As shown in Fig. 1, the apparatus consists of a rotary roasting furnace 1, supplementary roasting chambers 23, and filter chamber 30. Suitable oil burners, consisting of an oil pipe, an air inlet and steam supply pipe, are placed in the rotary furnace at 14 and in the supplementary chambers at 28. The filter chamber has vertical partitions with movable, fabric-covered doors 36. A fan 33 induces a draft through the apparatus.

In the first operation in the drum, most of the lead is converted into oxide and carbonate, and the complete oxidation of the lead is accomplished in the supplementary chambers. The lead fume is retained in the filter chamber by means of the fabric-covered doors which are shaken from time to time by mechanism 44-46. The product may be removed through doors 37. (1,088,041, Feb. 24, 1914.)

**Hydrometallurgical Copper Process.**—The MacKay process for treating copper ores is one of a number of hydrometallurgical schemes proposed in the last few years. In a recent patent specification, Mr. **Henry S. MacKay** discloses the following features of his process. The ore is roasted at a low temperature in the presence of sulphur, whereby some of the copper is sulphated and rendered soluble in water. The ore is then leached with water, and the solution electrolyzed, copper being precipitated and sulphuric acid formed. The electrolyzed solution is then used as an acid leaching liquor for the extraction of the balance of the copper remaining in the ore as oxide or other form insoluble in water. The inventor finds a solution containing 2 per cent sulphuric acid and 2 per cent copper as sulphate is the best leaching liquor, and he preferably conducts his roasting and electrolyzing process in such a way as to maintain a standard solvent and electrolyte. Should he prefer to work with chloride instead of sulphate solutions, he adds salt in the roasting process, thereby obtaining a chloride electrolyte. (1,094,371, April 21, 1914.)

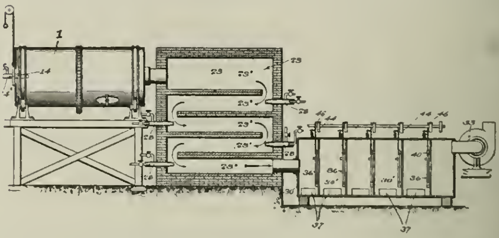

FIG. 1—APPARATUS FOR PRODUCING WHITE LEAD FROM ORES

**Sound Copper Castings.**—A method of producing castings of copper and silver, free from blowholes and of high electrical conductivity, is disclosed in a patent granted to Mr. **Charles L. Spinney**, of Lynn, Mass., assignor to the General Electric Co. Two or more parts of $B_2O_3$ for every 100 parts of the metal to be cast are placed with charcoal or other inert material in the bottom of a crucible. Copper is then placed on this mixture and superheated to a temperature of 1300 deg. C. It is covered with charcoal. The molten mass is then stirred with a graphite rod, whereupon the molten boric anhydride rises through the mass and removes dissolved and combined gases. Cast copper thus prepared has conductivity as high as 90 to 95% Matthiesen standard. (1,091,542, March 31, 1914.)

**Extraction of Nickel from Silicate Ores.**—Garnierite ores contain nickel in the form of a double silicate of nickel and magnesia. Garnierite occurs usually in a matrix of serpentine, with magnesia micas and other minerals which it closely approaches in specific gravity, so that ordinary methods of water concentration are ineffective. Messrs. **Henry L. Sulman** and **Hugh F. K. Picard**, of London, Eng., have devised and patented a process for the recovery of nickel from garnierite by use of a mineral acid in such quantity as to act as a selective solvent of the nickel.

It is impossible to dissolve all the nickel from garnierite by acid treatment with dissolving also a large quantity of magnesia. But if the quantity of acid be limited to about 25 per cent of the weight of the ore, undue solution of magnesia is avoided. Weathered ores yield more magnesia to the solution than do freshly crushed ores.

The material is crushed to 30 or 50 mesh and treated with concentrated sulphuric acid (and some salt if desired—25 per cent acid and 10 per cent salt). Enough water may be added to form a paste, and the well mixed mass is heated to 120-130 deg. C. The soluble salts are then extracted by water, preferably hot and slightly acid, and the solution removed by a filter press. The nickel is precipitated as hydrate from this solution by stirring in powdered MgO. (1,091,545, March 31, 1914.)

**Recovery of Tin.**—A simple method of producing commercial tin from the mixture of finely divided tin and tin oxide resulting from the treatment of tin scrap, Mr. William Hoskins, of Chicago, Ill., proposes a special form of furnace. The shaft is equipped with rows of tuyeres at three different levels. It is filled with carbon to a level above the upper tuyeres, the fuel being maintained in a state of incandescence throughout, but at a higher temperature in the upper part of the furnace. The metal mixture is charged onto the incandescent mass in a reducing atmosphere where tin oxide is reduced, and all the metal flows to the bottom of the shaft where it is withdrawn. (1,088,422, Feb. 24, 1914.)

### Metallurgical Furnaces

**Metallizing Furnace.**—The process of reducing an ore or oxide of a metal without fusion of the charge, known as metallizing, is receiving some attention as a possible means for producing an iron precipitant for copper solutions. A modified form of McDougall furnace is suggested and patented by Messrs. **E. P. Mathewson** and **Frederick Laist**, of Anaconda, Mont., as a suitable means of producing metallized iron, or "sponge" iron. According to the modification, a six-hearth furnace, for example, receives partly roasted ore, and completes the desulphurization and oxidation on the three upper hearths. On passing from the third to the fourth hearth, the ore receives an addition of crushed coal from a bin outside the furnace. The fourth and fifth hearths, where the reduction of iron oxide to iron takes place, are muffle hearths, suitably heated. Air is excluded from the three lower hearths and the final reduction takes place on the bottom hearth. The product is withdrawn from hoppers into which the ore flows from the bottom hearth. The roasting or oxidizing hearths are heated by oil burners, and the reducing hearths derive their heat from the admixed coal. Separate means are provided for withdrawing the different gaseous products from the upper and lower portions of the furnace. (1,094,802, April 28, 1914.)

**Heat Conservation in Roasting Furnace.**—According to a patent of Mr. **Utley Wedge**, of Ardmore, Pa., air heated by its passage through the rabble arms of the upper hearths of a furnace is delivered into the lower hearths through perforations in the rabble arms in those hearths. The heat derived from this air aids in maintaining combustion. (1,094,953, April 28, 1914.)

**Furnace for Volatilizing Sulphur from Sulphide Ores.**—In Fig. 2 is shown a modification of the Wedge furnace, in which the inventor has provided a construction for carrying on operations not easily performed in the ordinary furnace. Projecting upwardly from the hearths are annular ribs 11 which divide the hearths into inner and outer zones 12 and 13. The rabbles are adapted to work material in both zones. Different feed and discharge points are provided for the material going into and leaving each zone. Thus, for example, carbonaceous fuel may be burned in the outer zones and pyritic ore in the inner zones, the combustion of the carbon providing a reducing atmosphere in which sulphur may be volatilized. Steam may be introduced into those hearths where vaporization of the sulphur and oxidation of the metal is proceeding. This type of furnace is of interest in connection with the Hall process for roasting ores. (1,094,954, April 28, 1914.)

**Lining Furnaces.**—A method of lining and repairing furnaces of the open hearth type, while hot, is patented by Mr. **Byron E. Eldred**, of New York City. The method consists in projecting across a hot furnace, and to the point of use, a mixture of dolomitic lime and coal tar, or like substances, by means of a jet of products of combustion drawn from the stack of the furnace or other source. The material is protected against combustion of the binder in its passage across the furnace, and a dense, hard lining or patch can be readily made. (1,091,567, March 31, 1914.)

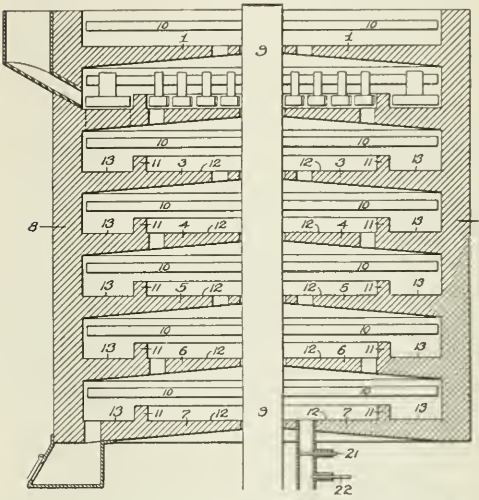

FIG. 2—FURNACE FOR VAPORIZING SULPHUR FROM SULPHIDE ORES

### Alloys

**Iron-Nickel-Copper Alloy.**—The use of Monel metal in producing both high and low range alloys of this type, as well as their production directly from ore containing nickel, copper and iron in the form of sulphides, is the object of a patented invention of Mr. **Guilliam H. Clamer**, of Philadelphia, Pa. To make a low range alloy from ore, a matter is first produced, which is roasted and then reduced, yielding a homogeneous alloy of the three metals. (1,086,314, Feb. 3, 1914.)

**Titanium Carbide.**—The production of a metallic compound useful in removing occluded impurities from metals, is patented by Messrs. **Auguste J. Rossi** and **William F. Meredith**, of Niagara Falls, N. Y. Iron, titanium oxide and carbon are charged in a crucible of an electric furnace. Conditions of time and temperature are maintained which result in the production of the most possible titanium carbide throughout the bath. The mixture is then promptly cast to avoid formation of graphitic carbon. The product is useful as a purifying agent when added to molten metals. (1,094,022, April 21, 1914.)

**Low-Carbon Ferro-Alloys.**—The production of ferrovanadium, ferro-uranium, ferro-chromium, etc., low in carbon, can be accomplished without using such agents as silicon, aluminium, ferro-manganese, etc., according to a patent granted to Mr. Warren F. Bleecker, of Canonsburg, Pa. The inventor first reduces a suitable metallurgical mixture to produce a ferro-alloy high in carbon, and then mixes with it a calculated amount of unreduced oxides and slag-forming material, so that the excess carbon in the alloy first produced will reduce the oxides subsequently added. The result is an alloy unusually low in carbon. (1,094,114, April 21, 1914.)

## Synopsis of Recent Chemical and Metallurgical Literature

### Gold and Silver

**Volatilization of Metals as Chlorides.**—Reference to the process of volatilizing metals from sulphide ores by roasting with salt has been made in this journal, April and May, 1913, pages 220 and 230, respectively, and in February, 1914, pages 71 and 137. Readers who are interested in this metallurgical process will find a valuable contribution by Mr. STUART CROASDALE, in *Mining Magazine*, March, 1914. The author was one of the inventors of the process in this country about fifteen years ago. Last year Mr. Ben Howe, of Australia, announced a similar process. In the article here referred to, Mr. Croasdale compares at great length the details of his own and Howe's work, and shows remarkable concordance of results and similarity of experience on the part of both. In concluding his comparison Mr. Croasdale says:

"It seems to me that no more convincing testimony of the metallurgical soundness of this process could be given than this independent duplication of my work from beginning to end by Mr. Howe, ten years after my work was published. As will be seen, the greatest difficulty in both cases was mechanical, namely, securing a satisfactory apparatus for collecting the fume. I believe this can now be easily solved." The last remark refers to condensation by means of a high-potential electric discharge.

**Benefits of Fine Grinding on the Rand.**—According to a note in the *South African Mining Journal*, the results obtained by the new tube mill plant of the Knights G. M. Company afford a good example of the benefits to be derived from fine grinding. Five tube mills, 16 ft. 6 in. by 6 ft., have been added to the mill equipment, with the usual accessory apparatus for classifying the feed and amalgamating the discharge. The full equipment of 245 stamps and five tube mills is now capable of crushing 45,000 tons of ore per month. The value of the tubes lies more in increasing the extraction than in raising the tonnage.

In September last, before the tube mills were used, the tailing sent to the dump had a gold value of $0.487 per ton. In the last quarter of the year, following the use of tube mills, the value of tailing was reduced to $0.262. This represents a gain of $0.225 per ton. Milling cost was increased by about $0.12 per ton. Further reduction in tailing value and working cost is anticipated.

**Sand Leaching at Oroya Black Range, Western Australia.**—The monthly *Journal* of the Chamber of Mines of Western Australia for January, 1914, contains an article on this subject by Mr. W. B. CHOMLEY. The ore is an oxidized quartz in which a large proportion of the gold is deposited on the cleavage planes of the shattered crystals. Fine crushing is unnecessary, and leaching is simple. The sand treated by leaching comprises 54 per cent of the ore milled. Crushing is done by stamps through 20 and 14-mesh screens, one battery which receives the greater proportion of soft ore being equipped with 14-mesh screens. Recovery by amalgamation, both on plates and in grinding pans, amounts to 65 per cent of the total.

The arrangement of the leaching plant is unusual. Eight vats are arranged in two rows of four each, elevated on timber framework, 12 ft. from the surface. Two collecting tanks on movable platforms run on a triple line of rails, one above each row of treatment vats. A central launder extends between and above the two rows of treatment vats, and has branch launders through which the stream of pulp can be diverted to the collecting tanks wherever they may be.

When a vat is to be filled the collector is run to a point above it, and the stream of pulp is distributed into the collector. The slime overflows to the vacuum-treatment plant. The collector being filled, it is allowed to drain for ten hours, after which the charge is shoveled into the treatment vat below, through two doors in the bottom of the collector. After leaching, the treatment vat is discharged in a similar manner into cars beneath. The accompanying table gives details of treatment.

Charge 85 tons dry sand

| Solution | % KCN | Time, | Hours | % KCN Coming Off |
|---|---|---|---|---|
| 25 Tons Strong | 0.25 | Pumping<br>Soaking<br>Draining | 5<br>8<br>19 | .01 to .05 |
| 20 Tons No. 2 Sump | 0.07 | Pumping<br>Soaking<br>Draining | 5<br>1<br>18 | .06 to .08 |
| 25 Tons No. 3 Sump | 0.03 0.05 | Pumping<br>Soaking<br>Draining | 5<br>1<br>18 | .04 to .06 |
| 25 tons No. 3 Sump | 0.03 0.05 | Pumping<br>Soaking<br>Draining | 5<br>1<br>18 | .03 to .05 |
| 30 Tons No. 3 Sump | 0.03 0.05 | Pumping<br>Draining<br>Vacuum | 5<br>21<br>4 | .03 to .05 |
| 125 Tons | | | 134 | |

No water wash is used, the weakest zinc-box tailing solution being applied for washing purposes.

The following is an average of costs for three months, and includes disposal of tailing.

| | Cents per Ton |
|---|---|
| Labor and salaries | 21.64 |
| Power | 4.04 |
| Repairs | 2.34 |
| Assaying | 2.04 |
| Cyanide | 16.32 |
| Sundries | 0.62 |
| Disposal of residue | 27.46 |
| Total | 74.46 |

The author calls attention to the value of allowing the charge to drain after each application of solution, thereby permitting oxygen to permeate the mass and aid in the solution of the gold. The practice of mixing some slime with sand is condemned on account of the practical impossibility of getting a permeable mass into which oxygen can enter.

### Zinc, Lead

**Preferential Flotation of Zinc Sulphide by the Horwood Process.**—Our last issue contained a note on the adoption of the Horwood process by the Zinc Corporation, Ltd., Broken Hill, N. S. W. The information there given is supplemented by the present review of an article by Mr. E. J. HORWOOD, published in the *Proceedings* of the Australasian Institute of Mining Engineers, No. 12, 1913.

The material being treated is a mixed zinc-lead flotation concentrate, too fine to be separated on concentrating tables. Hitherto it has been sold to zinc distillers as a low-grade concentrate. As it is not a desirable product, the producer is unable to obtain much value for the metals contained, particularly lead and silver. The importance of recovering these two metals in form suitable for lead smelting, as well as of raising the grade of the zinc content, is easily appreciated.

Being a preferential *zinc* flotation process, it offers advantages in treating slime concentrates produced from old dumps in which the lead particles have become slightly oxidized and are, therefore, not suited to a preferential *lead* flotation scheme. If the whole of the sulphides in any slime be first floated as mixed concentrates and then subjected to the Horwood process, a very high-grade zinc concentrate can be obtained, with a maximum recovery of the semi-oxidized lead and silver as a separate product.

A new feature of importance added last year was the preliminary washing of the mixed concentrates with clean water to remove soluble salts before roasting. This has resulted in diverting to the lead product a much higher percentage of the silver content, and has made possible an effective separation of lead and zinc with a lower degree of sulphatizing in the roast.

The Zinc Corporation's plant has a capacity of 500 tons per week. Pulp is thickened and then filter-pressed. The washing process mentioned takes place in the press, and the cake is finally discharged with about 10 per cent to 12 per cent moisture. It is then roasted in an Edwards furnace, in which the fuel consumption is 4.8 per cent of the ore charged. Coal is burned in six fireboxes arranged on both sides of the furnace. Draft is induced by a fan. The degree of sulphatization necessary for the process ranges about 30 per cent of the lead content.

The roasted product is then treated by flotation, whereupon the zinc floats and the lead and silver largely remain behind. Sulphuric acid consumed amounts to from 20 lb. to 27 lb. per ton. Eucalyptus oil is used at the rate of 1 lb. per ton, some being added to each of the ten boxes. Following are typical plant results:

| | Zinc, Per Cent | Lead, per Cent | Silver, Oz. per Ton |
|---|---|---|---|
| Feed to roaster | 39.0 | 16.0 | 18.0 |
| Zinc concentrate | 49.5 | 6.0 | 11.0 |
| Lead residue | 9.0 | 47.0 | 45.0 |

The financial result shows a net profit of about $15 per ton, considering the zinc concentrate as 71 per cent and the lead residue as 24 per cent of the original mixture.

### Reverberatory Furnaces

The utilization of the hot gases escaping from a reverberatory furnace, as a source of power, is general practice in connection with copper smelting. In a paper published in the Mining Magazine, February, 1914, Mr. **Arthur E. Williams** contributes calculations bearing on the amount of heat that may thus be utilized in connection with oil-fired reverberatories. He considers the case of a modern furnace, 100 ft. long by 19 ft. wide, using crude oil of the following composition: 84.2 per cent C, 12.4 per cent H, 3.4 per cent O, having a calorific value of 19,296 B.t.u. A summary of his calculations leads him to the conclusion that a properly designed and operated waste-heat plant in connection with oil-fired reverberatories should yield in steam the equivalent of 50 per cent of the calorific value of the oil. Turbo-generators would yield 0.36 kw. or 0.48 electrical hp. for each pound of oil burned in the furnace.

## Notes on Chemistry and Metallurgy in Great Britain

*(By Our Special Correspondent)*

### Tungsten and Nickel High Speed Steels

A paper by Prof. J. O. Arnold and A. A. Reed on "The Carbides of Tungsten and Nickel Occurring in Steels" was recently read before the Institution of Mechanical Engineers.

In their introductory remarks the authors mentioned that although the importance of the subject might not be manifest to engineers, yet the work done by Abel and Deering on carbide of iron was a great cornerstone in the metallurgy of steel, and, therefore, for the benefit of engineers; because it appeared to them that advances in the metallurgy of steel had been followed by marked advances in mechanical engineering. It was not possible to acquire a complete knowledge of high-speed steels until the state of the existence of the carbides therein was well understood; and any importance which attached to the present paper was due to its dealing with tungsten, the essential element of high-speed steel, and with nickel, an equally vital component of the best structural steels.

The tungsten steels employed in the investigations contained from 0.67 to 0.73 per cent of carbon and from 2.38 to 26.29 per cent of tungsten. The carbides were separated by an electrolytic method, and the results showed that in the steel, with 0.7 per cent of carbon and 9.74 per cent tungsten, practically the whole of the iron carbide had disappeared, and the carbide of tungsten nearly corresponding to the formula $W\,C$ had replaced it. That tungsten carbide should theoretically contain 93.88 per cent tungsten and 6.12 per cent carbon. In the case of steels containing 14.96, 21.15 and 26.29 per cent tungsten, the carbon falls and the iron rises as the tungsten rises, and this leads to the idea that a stable tungstide of iron exists with the carbide of tungsten.

In preparing ferro-tungsten at Sheffield University it had been found that the high specific gravity of this tungstide prevented the production of a homogeneous alloy in the crucible. When making pure 40 to 50 per cent ferro-tungsten from metallic tungsten and Swedish bar iron, it is always found that there is a fluid part which pours easily and a liquated portion at the bottom which can hardly be poured at all on account of its very high solidifying point. It adheres to the crucible in a pasty state, and when cold is only drilled with great difficulty by an especially hard drill which easily cuts very hard chilled white iron, and its hardness, therefore, must be nearly that of feldspar. In one melt the fluid portion of low solidifying point contained 38.2 per cent of tungsten and weighed about 14½ lb. The portion of higher melting point which remained in the crucible contained 52.3 per cent of tungsten, and its weight was about 13 lb. This latter metal has a composition approximately to the formula $Fe\,W$. On account of this liquation it is quite impossible to prepare a homogeneous large bar of high-speed steel—for example, from a 2-ton ingot—the bottom of the ingot always contains considerably more tungsten than the top, and the larger the proportion of tungsten employed the greater is the difference between the tungsten content at the top and the bottom of the ingot.

Photo-micrographs of tungsten steels clearly showed the presence of three new components; namely, tungsten pearlite, tungsten cementite and tungsten hardenite. The pearlite is usually of a fine granular or minutely laminated structure, characteristic of the sorbitic variety of pearlite; the cementite was obtained in nodules, similar to iron cementite, by annealing the tungsten alloys, owing to the segregation of the $WC$ of the pearlite. The hardenite forms slowly and progressively from the pearlite. Beginning about 830 deg. C. the transformation is apparently complete at about 1150 deg. C.

The steels, which contained 14.96 and 21.15 per cent of tungsten with 0.7 and 0.73 per cent of carbon respectively, were easily filed when quenched at 860 deg. C.; when quenched at 1000 deg. C. they were hard, but could still be filed; but when quenched at 1190 deg. they were sufficiently hard to strip the files.

These facts go to prove the progressive formation of tungsten hardenite; and though these facts have been known for possibly twenty years to practical men, the authors believed that the scientific explanation was given for the first time in their paper.

With regard to nickel steels, the authors were of opinion that in ordinary manganese structural steels containing up to 7 per cent of nickel, the nickel is not combined with the carbon, but forms alloys with the iron and the manganese, and that a definite alloy of iron and nickel is formed corresponding to the formula $Fe_7Ni$, a substance which is possibly one of the most remarkable in the metallurgy of iron.

Sir Robert Hadfield suggested they should make a set of nickel alloys, as free as possible from carbon, silicon and manganese. He predicted that alloys of nearly pure iron and nickel would show a critical mechanical point at something between 11 and 15 per cent of nickel. Experimentally the tests fulfilled the prediction, but the effect of carbon and silicon and higher manganese on such alloys was to produce surprising ductility, giving 11 per cent elongation, 46 per cent reduction of area, a bending angle of 167 deg.; a yield point of 39 tons and a maximum stress of 88 tons per square inch for the 13 per cent nickel steel.

A nearly pure 7 per cent nickel-iron has almost the same mechanical properties as an iron containing 33.5 per cent nickel, namely, a yield point of 30 tons, a maximum stress of about 38.5 tons per square inch; an elongation on 2 in. of about 30 per cent, and a 37 per cent reduction of area. A curve of tenacity for nearly pure nickel iron with observation points at 7, 13 and 33 per cent nickel the greatest stress is shown at 13 per cent, which corresponds to the formula $Fe_7Ni$. The consequent existence of a definite alloy of iron and nickel having that composition is extremely possible.

## Scottish Shipbuilding

During February 27 vessels with a tonnage of 55,687 were launched from Scottish yards, making a total of 46 vessels and 86,500 tons for the two months, out of which 32 vessels of 71,354 tons were built on the Clyde.

Although new orders placed are far from numerous there is no immediate probability of work slackening in the yards.

## Company Meetings

*Sir W. G. Armstrong Whitworth & Co.*

Annual general meeting, April 18. A total dividend for the year of 2/6d. per share on the ordinary shares was declared and £56,559.14.9 went for dividends on the preference shares, the total sum thus absorbed being £568,122.4.9, leaving a balance of £323,716.2.3 to be carried forward to next year's accounts.

*Mason & Barry.*

Annual general meeting, April 27. A dividend of 7/- per share was declared, the same as last year. After placing £20,000 to reserve for contingencies, and £1,000 as usual to Staff Pension Fund, the balance carried forward was £15,550, as against £25,148 last year.

*Consolidated Malay Rubber Estates.*

Annual general meeting, April 23. Total dividend of 50 per cent for the year was declared, and it was announced that the cost of production had been materially lowered.

*Bell's United Asbestos Co.*

Annual general meeting, April 20. The ordinary dividend declared is the same as for the last four years, namely, 12½ per cent; £5,000 goes to reserve, as against £15,000 in the previous year, 1912, and more than £3,000 more is carried forward.

*Brush Electrical Engineering Co.*

Annual general meeting, April 20. The chairman announced that the business of the company had improved very satisfactorily. It was proposed to reduce the preference shares to a nominal value of 7/- and the ordinary shares to a nominal value of 5/- each, with a view of being in a position next year to pay a dividend on the reduced capital.

## Market Prices

April, 1914

| | £ s. d. |
|---|---|
| Aluminium ingots, ton lots | 86. 0. 0 |
| Alum, lump, loose, per ton | £5.5.0 to 5.10. 0 |
| Antimony, Star Regulus, ton | 28.10. 0 |
| Borax, British refined, crystal, cwt | 17.10. 0 |
| Copper sulphate, ton | 21.15. 0 |
| Caustic soda, 70% ton | 10. 0. 0 |
| Copper ore, 10% to 25% per unit | 10/9 to 11. 3 |
| Ebonite rod, lb | 4. 6 |
| Hydrochloric acid, cwt | 5. 0 |
| India-rubber, Para, fine, lb | 2.11½ |
| Mica, in original cases, medium | 3/6 to 6. 0 |
| Petroleum, Russian spot, gal | 9¼ |
| Quicksilver (Spanish) bottle | 7. 0. 0 |
| Sal-Ammoniac, cwt | 2. 2. 0 |
| Sulphate of ammonia, ton | 12. 3. 9 |
| Sulphur, recovered, ton | 5.10. 0 |
| Shellac, cwt. | 3.15. 0 |
| Platinum, oz., nominal | 9. 5. 0 |
| Tin ore, 90%, ton | £96.0.0 to 98. 0. 0 |
| Zinc, Vielle Montagne | 25.12. 6 |

Copper opened £64.15.0 and soon hardened, being £65.18.9 by the 8th. After the holidays it was lower at £64.5.0 (14th) and £64.17.6 (15th), falling away to £64.7.6 (20th) and, after a short recovery, to £63.5.0 (24th). Since slightly higher and closing £64.0.0.

Tin opened £172, but fell away till it touched £167.7.6 (8th). After the holidays it opened £166, weakening for a few days, then regaining to £166.5.0 on the 17th. It declined sharply later, reaching £161.10.0 on the 22d and £155.10.0 on the 24th, closing £156.15.0.

Lead opened £18.10.0 and rose to £18.15.0, which price was maintained from the 7th to the 16th. It then fell to £18.10, remaining so till the 23d. On the 24th again rose to £18.15.0, and by the 27th had reached £19.15.0 and closes £19.5.0.

Hematite has been steady at 61/- and closes same price.

Scotch pig opened 56/- but rose smartly to 57/6 (7th), after the holidays (14th) it opened 57/3 and then fell slowly to 56/7½ on the 22d, recovering to 56/10½ on the 23d. Closes 57/6.

Cleveland opened 50/- and rose to 51/6 by the 7th, thence fell to 51/3, which was maintained till the 14th; on the 15th 50/10½ was registered, the price then fell off to 50/7½ on the 22d, after which a recovery to 50/10½ on the 23d. It closes 51/4½.

## Differences

| Higher | £ s. d. | Lower | £ s. d |
|---|---|---|---|
| Aluminium, ton | 1. 0. 0 | Copper sulphate | 15. 0 |
| Shellac, cwt | 3. 6 | Sul. of Ammonia | 3 6 |
| Scotch pig | 1. 6 | India-rubber | 0½ |
| Cleveland | 1. 4½ | Tin ore | 11. 0. 0 |
| | | Copper | 15 0 |
| | | Tin | 15. 0. 0 |

---

The **American Institute of Mining Engineers** will hold its autumn meeting in the week from Monday, Aug. 10, to Saturday, Aug. 15, in Salt Lake City, Utah.

## The Lavoisite System of Generating Oxygen

For the art of autogenous welding, and the cutting of steel, there are at present four commercial methods of generating oxygen. Probably the user of oxygen for such purposes is most familiar with bottled oxygen, as produced by the Linde process.

Second in volume to the bottled oxygen as produced by the Linde process is that produced by the decomposition of water, which is also distributed in bottles, under high pressure, and is commercially known as electrolytic oxygen. Electrolytic cells are now also installed in manufacturing plants, making it possible for such manufacturers to produce their own oxygen, thereby doing away with the inconvenience incident to the use of bottled oxygen.

The production of oxygen by the use of chlorate of potash and manganese dioxide is now widely known, and there are several small installations of such plants throughout the country.

The Lavoisite system, though not so well known, is in fact a much older method of producing oxygen than any of the previously mentioned systems. Its introduction into general use for the generation of oxygen, in connection with the art of oxy-acetylene welding, has been slow, for the reason that up to within a comparatively short time a practical commercial generator had not been designed that would work successfully in connection with this method of generating oxygen, and in this respect the Lavoisite process is similar to a great many other chemical processes, the commercial efficiency of such depending entirely upon a design of apparatus that will carry out the chemical reactions in an efficient and reliable manner.

Lavoisite, so called in honor of the celebrated French chemist Lavoisier, whose name is so intimately associated with oxygen, is a specially prepared calcium hypochlorite, which, when put into solution, a suitable and proper amount of catalyzer being added and the solution simultaneously being heated to 90 deg. C., rapidly generates oxygen of a purity that is unsurpassed by any of the processes that are now in commercial use. Tests from plants in operation showing the oxygen from Lavoisite to be practically 100 per cent pure.

In the early days of the art of oxy-acetylene welding the purity of the oxygen was not given much thought. It soon became evident, when the users of oxygen became familiar with the art of autogenous welding, that the purity of the oxygen was of the greatest importance, as the results obtained by the use of pure oxygen against impure oxygen were such that even a slight difference of only 1 per cent would show inferiority in the quality of the weld, the time to accomplish the work, the amount of oxygen and acetylene used also being affected. This is most pronounced in the cutting of steel, where a difference of only a fraction of 1 per cent will greatly affect the time of cutting and quantity of oxygen used.

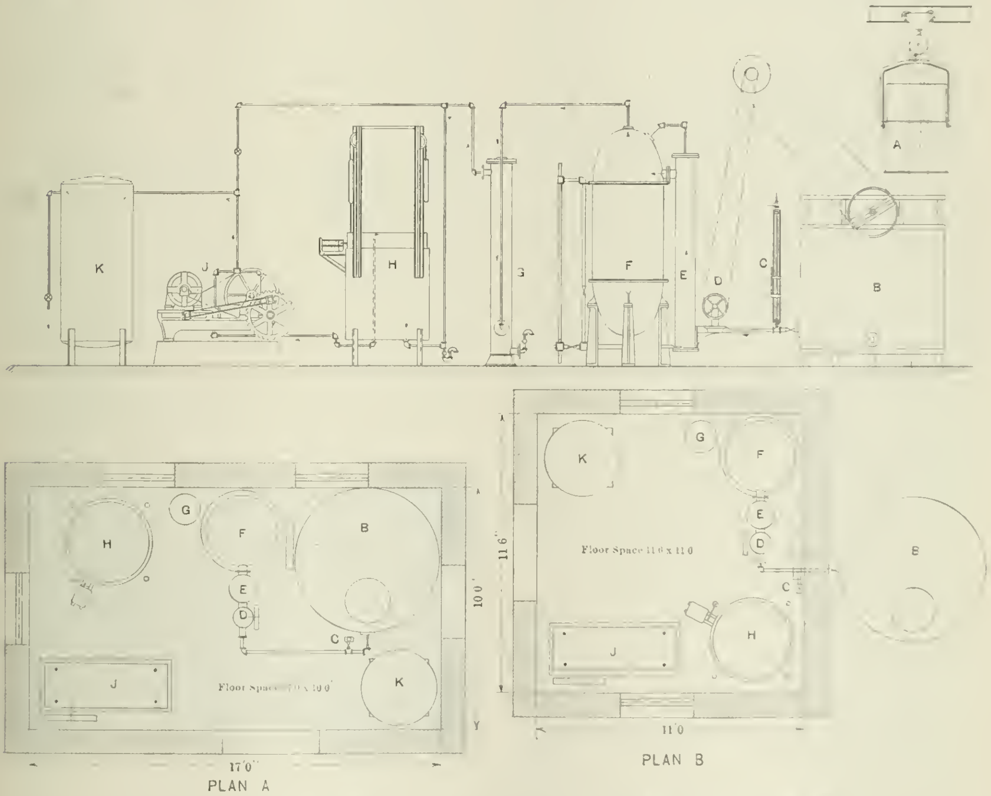

FIG. 1—PLANS AND VERTICAL SECTION OF LAVOISITE OXYGEN-GENERATING SYSTEM

A loader, B mixing tank, C indicator, D pump, E heater, F generator, G scrubber, H gas-holder, J compressor, K pressure-tank.

The operation of the Lavoisite generator is best described in U. S. patent No. 1,031,017, covering this apparatus, the efficiency of its operation depending upon the regulation and direction of the flow of the Lavoisite solution through the apparatus.

Lavoisite is shipped in large hermetically sealed steel drums, holding about 800 lb. of Lavoisite. The Lavoisite is charged into tank *B*, shown in Fig. 1. A loading device of special design is furnished for lifting the drums from the floor and conveying them to the mixing tank *B*. The loader is equipped with doors that open downwards upon releasing a catch, thereby discharging the contents of the drum into the mixing tank. Sufficient water is then added to bring the mixture up to the required consistency. An indicator *C* shows the required amount of water to be added, according to the weight of Lavoisite placed in the mixing tank. This indicator does away with any necessity of calculation on the part of the attendant in charge of the plant as to the proper strength of the Lavoisite liquor in the mixing tank, which it is essential to keep within a few degrees of the correct gravity.

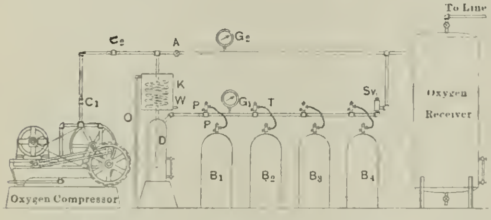

FIG. 2—METHOD OF COMPRESSING LAVOISITE OXYGEN INTO CYLINDERS FOR PORTABILITY IN USE THROUGHOUT CUSTOMER'S PLANT

A globe valve on receiver line, $B_1$, $B_2$, $B_3$, $B_4$ oxygen bottles, $C_1$ vertical ball check valve, $C_2$ horizontal swing check valves, D separator, K condenser, $G_1$ high pressure gauge, $G_2$ low pressure gauge, O water overflow, P pressure valves, $S_v$ savety valve, T copper tubes, W water inlet.

Mixing tank *B* is equipped with an agitating device to assist the Lavoisite in going into solution, and during the generation of oxygen this agitator is slowly, yet constantly, stirring the contents of the mixing tank.

The liquor passes from the mixing tank to the pump *D*, which forces it into heater *E*. Connected with pump *D* is a small pump for simultaneously forcing catalytic liquor into the heater *E* in the correct proportion to Lavoisite liquor being pumped by pump *D*.

The heater *E* is equipped with a thermostat which controls the amount of live steam admitted to heat the liquor coming from the pump, so that regardless of the speed of the pump over a given range, the temperature of the heater remains constant. The Lavoisite and catalytic liquor enter at the bottom of the heater and are brought quickly up to a temperature of 90 deg. C., when oxygen is rapidly generated; it is here necessary that the liquor in the heater travel in the same direction as the liberated oxygen.

About 90 per cent of the reaction takes place in the heater. The oxygen liberated passes through a pipe connected to the top of the heater to the generator *F*. The partly finished liquor passes through a pipe in the side of the heater to the generator *F*, within which the reaction is completed, the spent liquor overflowing through the pipe shown at the side of the generator. The passage of the liquor through the generator is in reverse direction to that of the oxygen; consequently the liquor that has been unacted upon, in its passage through the heater, comes into more intimate contact with the catalyzer in the generator *F*, with the result that the liquor leaving the generator is entirely depleted of its oxygen content.

The oxygen leaving the generator passes through the scrubber, or cooler, *G*, where it is reduced in temperature, and any moisture mechanically carried over from the generator is condensed out. From the scrubber the oxygen passes to a gas-holder *H*, the bell of which is counterbalanced.

The rise and fall of this bell actuates a tank switch, which automatically cuts in and out the compressor *J*. The pressure of the oxygen up to the compressor is slight, in practice about equal to a column of water 2 in. high. The compressor raises this pressure up to any desired point, usually 75 to 100 lb., and stores the oxygen at this pressure in the pressure tank *K*.

A pipe shown at the left of the pressure tank conducts the oxygen to any point where it is desired to use it, the usual reducing valves being placed on outlets from this pipe to reduce the pressure suitable to the torch being used.

The capacity of the Lavoisite generator is very flexible, the quantity of oxygen produced being controlled by the speed of the pump *D*, which is fitted with a cone pulley, making it possible to generate oxygen from 50 cu. ft. per hour to 500 cu. ft. per hour. This is of great advantage to the welder, as it enables him to keep pace with his work by simply speeding up the apparatus, doing away with the necessity of having numerous or large tanks of oxygen under high pressure.

Tests of the oxygen have shown a purity as high as 99.9 per cent. The purity of Lavoisite oxygen is such, in fact, that for the cutting of metal it is not necessary to run the pressure above 50 lb. for all ordinary work. If, however, it is desired to compress to a higher degree than that usually carried in the pipe lines, an outfit such as is shown in Fig. 2 is used, which allows the consumer to compress the oxygen into bottles, up to a reasonably high pressure, 300 to 400 lb., for portable and local use about his plant.

Plans of typical installations of Lavoisite plants are shown in Fig. 1. It will be seen to be possible to place in a building 11 ft. square a generator capable of producing 500 cu. ft. of oxygen per hour.

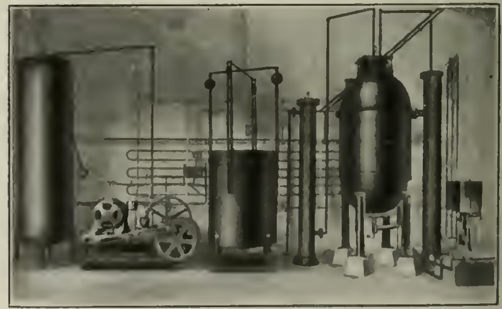

FIG. 3—LAVOISITE OXYGEN-GENERATING PLANT, 50 TO 500 CU. FT. OXYGEN PER HOUR

The operation of the generator is automatic and continuous, so long as it is supplied with liquor from the mixing tank *B*, and this tank can be charged from time to time without affecting the generator. In shutting down it is necessary only to stop the feed pump *D*, when the generation of oxygen ceases.

Fig. 3 is a view of an installation with a capacity of from 50 to 500 cu. ft. of oxygen per hour. The mixing tank is here not shown, it being placed on the outside of the building. The pipe shown projecting through the wall at the right in the photograph connects with mixing tank. The illustration clearly shows the several parts of the apparatus. There are, however, numerous pipes shown in the photograph having nothing to do with the Lavoisite generating outfit, they being water pipes for heating and water supply to the welding shop.

Lavoisite is noncombustible, so that large quantities can be stored without danger. This makes it possible for the user to have at his command his supply of oxygen in a convenient form to meet the varying demands of his daily needs. Sufficient quantity of Lavoisite is usually charged into the mixing tank in the morning to last throughout the day; this is a matter of a half hour's work, so that it is not necessary to employ additional labor to do this work, the ordinary shop helper being fully capable of charging the Lavoisite plant.

Lavoisite is sold by the Castner Electrolytic Alkali Company under an agreement with the purchaser that every pound of Lavoisite will produce 1 cu. ft. of oxygen, when used in the generators designed for its use and operated according to instructions given. The apparatus, and all pertaining thereto, are manufactured by the Castner Electrolytic Alkali Company, Niagara Falls, N. Y. Some of the plants now installed by this company are capable of generating upwards of 5000 cu. ft. of oxygen per day of ten hours.

---

The **New York Section** of the **American Electrochemical Society**, in its meeting on May 22, elected Dr. Colin G. Fink chairman for the coming year and reelected Mr. H. B. Coho secretary and treasurer. A vote of thanks was extended to the retiring chairman, Mr. Lawrence Addicks, now in Douglas, Arizona, for the extraordinarily effective work done by him for the society during the past year.

**Detachable Link-Belt** is the subject matter of a very interesting and freely illustrated book just issued by the Link-Belt Company of Chicago as Section A of Catalog 110. Detachable link-belt was invented by William D. Ewart in 1873, and from that time the original has been manufactured solely by the Ewart and Belmont Works of the Link-Belt Company.

**Feed-Water Difficulties.**—"The problem of suitable feed water, although less serious in New England than in other parts of the country, is still a trouble maker in many plants. The formation of scale and the softening of water are due to the simplest of chemical reactions, and by an analysis of the water a competent chemist can readily predict in advance the proper amounts of suitable chemicals necessary to prevent scale or corrosion, and not only save the company the expense of frequent boring and replacing of tubes, but obviate the necessity of attempting to force heat through the same substance with which many of your steam lines are insulated. The service of a chemist," said Mr. Carl F. Woods, secretary of the firm of Arthur D. Little, Inc., of Boston, when recently speaking before a group of street railway operators, "would prevent the purchase of a special compound at $1,000 a year which consisted of 97 per cent water and 3 per cent molasses, or obviate the necessity of purchasing a mixture of soda ash, tannin and water under a brand name at 8 cents a pound when the principal ingredient can be obtained for 1 cent a pound."

**Lead and Zinc in Kansas and Arkansas.**—The value of the lead and zinc produced at mines in Kansas in 1913 was $1,343,432, compared with $1,680,744 in 1912, according to J. P. Dunlop, of the United States Geological Survey. In Arkansas the value was $55,120 in 1913, compared with $106,014 in 1912.

## Accelerators for Gasoline Gas Plants

BY C. J. BARTON

The laboratory in which the writer worked was equipped with a gasoline gas machine. In the summer no trouble was experienced in securing a good gasoline gas for the laboratory but in winter the gas became so weak that it would hardly burn. The apparatus consisted of a large drum-shaped low-pressure air-compressor which compressed air to about 10 in. of water. The drum was driven by a large weight which was periodically wound up by hand. The gasoline was kept in a large underground tank outside of the laboratory. The gas machine was a surface machine, the air from the compressor passing over the surface of gasoline in the tank then through a pressure regulator, where the pressure was reduced to about 1 in. of water, then into the gas line.

It was almost impossible to do any analytical work with the weak gas obtained in the winter time so the writer made what was termed "accelerators" to enrich the weak and almost unburnable gas into a good gasoline gas.

The "accelerators" consisted of a wide-mouthed heavy glass bottle with a two-hole rubber-stopper fitted. The bottle would hold, when full, about a pint of gasoline. The rubber stopper was fitted with two pieces of glass tubing bent at right angles at their upper extremity, to fit into the gas hose.

One glass tube was about 6 in. in length and led the weak gas from the line down into the bottle to the surface of the gasoline, the other tube was just long enough to reach through the rubber stopper and carried the enriched gas through a short length of gas tubing to the burner. The bottle if filled with gasoline in the morning would enrich the gas for a half day or so. The object of having the one piece of glass tube longer than the other was to make it possible to follow the surface of the gasoline down into the bottle as it was evaporated. This also furnished a means of regulating the amount of the enrichment the weak gas received. A bulb was blown in the glass tube leaving the "accelerator" in which glass wool was inserted to prevent the flame following back into the bottle from the burner on turning the gas off. One of these accelerators was made for each burner used.

It was noted on using these "accelerators" that the more volatile and lighter constituents evaporated first and left a heavier portion behind in the bottle which amounted to from 50 to 60 per cent of the original volume of the gasoline. This residuum very much resembled kerosene in appearance but would not burn when poured on the cement floor. It could be completely vaporized, however, if warmed to the boiling point by setting the "accelerator" in hot water or on a radiator. Ordinarily in using the "accelerator" when 40 to 50 per cent of the gasoline had evaporated the remainder was thrown out and more gasoline was put in.

These "accelerators" have been in use about three months and have proved a valuable accessory to an independent gasoline gas plant.

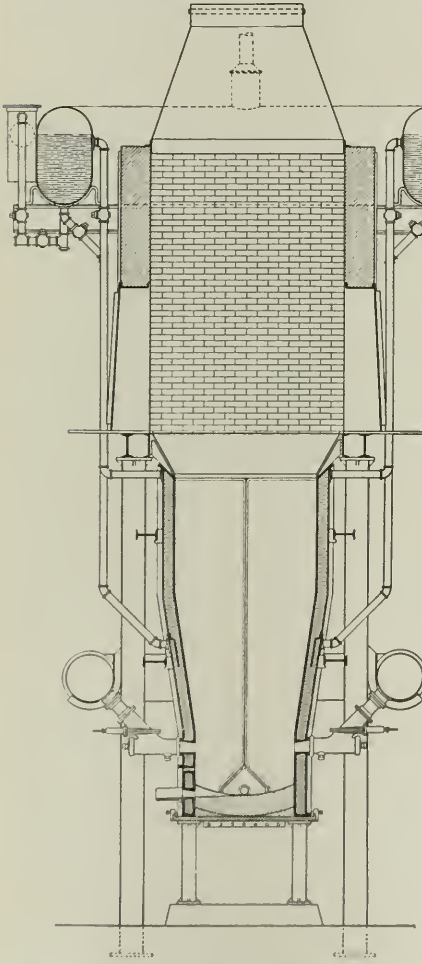
---

The **Munning-Loeb Co.**, of Matawan, N. J., have just issued Bulletin 500 on their line of plating and industrial brushes. The book contains information on brush manufacture from the making of the block, selection and origin of stock to the final finish. Operating characteristics of the several brush materials and their adaptability to certain classes of work are briefly discussed.

## The Vaporization of Jacket Water

Catalog No. 12-F, just issued by the Colorado Iron Works Co., of Denver, Colorado, and entitled "Some Details as to Smelting Practice and Equipments," contains an exceedingly interesting chapter on the Vaporization of Jacket Water, which deserves the full attention even of experienced smelting men. We herewith reproduce this chapter practically in full.

In many localities the matter of jacket water supply is a very serious one, either from absolute scarcity, expense of pumping, or cost, where it has to be purchased. This led the Colorado Iron Works to a serious study of the problem, and their solution of it, the Nesmith patented system of vaporization, not only reduces the amount required to one-eighth of that ordinarily necessary, but also provides what experience has proved to be the best method of cooling even where water is abundant.



NESMITH PATENT JACKET WATER VAPORIZER

Some smelter operators run so much water through their jackets that it is discharged at a temperature much below the boiling point. Their reason for this is primarily to obviate the close attention otherwise necessary and they also think that they are on the safe side and that the cooler jackets are run, the better. This is a mistaken idea. Aside from the fact that an important loss of heat, which must be compensated for by additional fuel, results from such practice, the life of the jackets is much greater when they are run with the discharge as near the boiling point as possible. Both cast iron and steel have greater tensile strength and a higher elastic limit at 400 degrees Fahrenheit than at lower temperatures, and the hotter jackets can be kept, the more durable they will be. More cast-iron jackets are broken and steel jackets damaged by running an excess of cold water through them than in any other way. The sudden admission of cold water to a cast-iron jacket which has been running hot is especially liable to cause its failure.

As indicated by its name, the principle upon which this system is based is to take advantage of the latent heat of vaporization of water. The magnitude of the saving thus effected is plainly apparent in the following figures.

The heat absorbed by one pound of water at 212 degrees F. in passing into steam is 966 British thermal units, the application of this amount of heat being necessary to produce the change from liquid to gaseous state. In cooling jackets in the ordinary manner, the heat units carried off by the water equal the number of degrees difference in temperature between the feed and discharge, and assuming the feed water temperature to be 62 degrees and the discharge 212 degress, the maximum possible heat abstraction of one pound of water is 150 units.

If now the pound of water be completely vaporized, there will be 966 units added to the 150 units, or a total of 1,116 units of heat utilized. This shows the amount of water necessary when vaporized to be, $150 \div 1116 = 0.1344$ or 13.44 per cent. of that necessary where the water is discharged as water at the boiling point. The results in actual practice are better than this, for the discharge of the water at the boiling point has been assumed, and this is a condition which is never even closely approached, owing to the danger of supplying insufficient water.

The water obviously can not be boiled in the jackets, but our system provides means whereby full advantage is taken of the latent heat of vaporization without danger of overheating any jacket—in fact, with absolute assurance of all jackets being continuously and evenly cooled.

The vaporizing system operates in a manner similar to the hot-water system ordinarily installed in residences, in which the water back in the range corresponds to the water jackets of the blast furnace. The arrangement of piping is similar and circulation of the water is maintained in the same way.

For use with this system the jackets are the same as with the ordinary overflow system except that the pipe connections are larger in order to reduce friction The pipes lead to a closed drum surrounding the furnace, the feed pipes being connected to the bottom and the discharge pipes entering the drum slightly below the water level. The tendency of the hot water to rise and cold water to find the lowest level maintains a very effective circulation and any boiling takes place in the drum, not in the jackets, because the water in the jackets is under sufficient head to cause the boiling point to be several degrees higher than in the drum which is only under atmospheric pressure. A gauge glass indicates the water level, an automatic float valve controls the admission of water to replace that evaporated, and a vapor escape pipe provided with an exhaust head conducts the steam formed to the atmosphere.

A smelter superintendent, after operating a furnace provided with this vaporization system for several months, recently gave the following information on jacket water consumption:

"The furnace proper is using about 90 gallons per hour. I have not had time to figure this back to gallons per square foot of jacket area, but as the jacket area on this furnace is large, it should show a very low water consumption per square foot. * * * It is without question the best water system for a blast furnace I have ever seen. All jackets are always at a uniform temperature; with a proper float valve absolutely no attention is required. In blowing-in we never think of the water, while with the old-style overflow system it generally keeps one man busy to keep from burning a jacket. In places where water is scarce a more elaborate condenser on the exhaust head would save nearly all the water. Another very good feature is the fact that different furnace men have their own ideas about jacket water—one wants to run his water cool or cold and another hot with no two jackets the same, while with this system it absolutely cuts out the 'personal element' and the jackets must have a decided benefit from the constant temperature."

Jacket water consumption is usually determined in gallons per minute, to avoid large figures, but as is evident from the above quotation, gallons per hour would be a more convenient measure of comparison were the vaporizer system in universal use. However, on the customary basis, the exposed jacketed surface of the above furnace being 414 square feet, the water consumption was 0.00362 gallon per minute per square foot of jacket area. This was a copper matting furnace. Another user of the vaporizer system, operating a lead furnace, reported a water consumption of 0.0113 gallon per minute per square foot jacket area, but this vaporizer was run without an automatic float valve and loss of some water was consequently unavoidable.

Comparison of the above with published figures for Cananea, 0.616, and for Granby, 0.31, shows an actual saving far above the theoretical, and brings out strongly the magnitude of the waste of water in cooling jackets in the ordinary way. At Granby, the discharge from the upper jackets was the feed for the lower jackets, which accounts for the large economy shown over Cananea, the amount of water used at Cananea being about what is ordinarily required.

The jacket water is commonly run into settling ponds where it is cooled and reused, but there is great loss from evaporation and seepage, to say nothing of the expense of pumping. The installation of the vaporizing system will cost less than settling ponds and it entails no continual expense, as for pumping. In addition, it provides cooling means in every way superior to the ordinary overflow method.

---

**Radium Prices.**—At the Senate hearing on radium Mr. Thomas F. V. Curran, of Placerville, Colo., who is engaged in mining and shipping carnotite ores, stated that he sold his product to Armet de Lisle, Nogent sur Marne, France, where he obtained the best prices. Payment is made on the basis of hydrous radium bromide, $RaBr_2.2H_2O$, delivered, at the rate of 100 francs ($19.30) per milligram per ton, for ore containing from 6 mg to 10 mg per ton; over 10 mg per ton a bonus of 20 per cent is paid. As the ore contains from 3 mg to 4 mg $RaBr_2.2H_2O$ per ton, the price received ranges from $60 to $80 per ton of ore. Mr. W. L. Cummings, another shipper from Placerville, stated that he was paid $2 per pound for the uranium oxide contained, f.o.b. Placerville. On 2 per cent ore, which is average shipping grade, the price would come to $80 per ton.

## Electric Furnace Regulator

In the interesting American Electrochemical Society paper of Mr. Robert Turnbull, of Welland, Ontario, Canada, noticed on page 333 of our May issue, a number of important principal advantages were mentioned which can be obtained in electric furnace operation by the use of nearly all kinds of regulators.

Among special advantages which may be derived from the use of the Thury regulator, Mr. Turnbull mentioned the following:

1. The damping devices employed only permit the regulator to act, when it is necessary for it to do so. Sudden changes and changes of short duration will not put the regulator in action. This in itself is very important, as not only is there a great saving on the wear and tear of the electrode hoisting mechanism, motors for driving same, etc., but the current is kept more uniform by avoiding the regulation of such changes.

2. This regulator can handle any amount of power for regulating purposes, without in any way impeding the free play of the controlling mechanism, which is only in contact with the power mechanism for exceedingly short periods of time and is otherwise perfectly free.

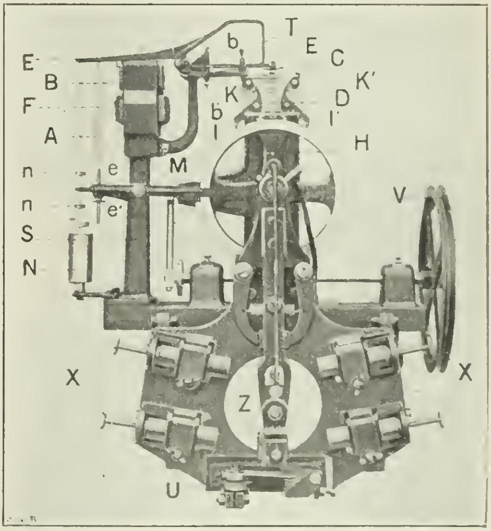


FIG. 1—THURY REGULATOR

3. The regulator requires no attention whatever, and with the exception of the oiling of the moving parts once a week, can be practically ignored.

4. Great variations of current can be automatically obtained by use of this regulator.

5. The intermittent action of the contact-making arm is important, as the regulation is thereby prevented from being carried too far in one direction and a high load factor is assured at all times and uniform current on the furnace.

The Thury regulator is the invention of Mr. R. Thury, of Geneva, Switzerland. It was first applied to electric furnaces in 1901 by Dr. Paul Heroult to his first steel furnace:

The principal parts of the regulator (Fig. 1) are the fixed coil F, the movable coil B, the rocking lever E, the spiral spring A, the dashpot or damping device

N, the abutment knives C, the tappets K, the pawls I, the tappet wheel H, the copper contacts Z, the carbon contacts, and the short-circuiting device U.

When the current operating the furnace is at its normal value, the rocking lever E is held in equilibrium by the pull of the spring A, and the magnetic force of the fixed coil F acting on the movable coil B. The knives fixed to the rocking lever in this position swing clear of the tappets K. When a variation of sufficient duration occurs on the furnace, the movable coil will either be pulled to or pushed away from the fixed coil, depending on whether the current has decreased or increased on the furnace, and the rocking lever will swing either the one or the other of the knives against one of the tappets K. The tappet is pushed from its position, releases the pawl I which falls into the notch in the tappet wheel. The arm carrying the copper contacts, which is fixed to the tappet wheel shaft, will swing either to the right or to the left, bringing the copper contacts against the carbons, and current will immediately flow to the terminals of the winch motor.

The Cuenod Company of Geneva, Switzerland, who now control the manufacture of the Thury regulator, have added to the regulator a series of apparatus, which taken together form a very complete regulator system. This system can best be described by a reference to Fig. 2.

It consists of the following:

1. A winch T R for raising and lowering the electrodes.

2. A double-throw switch with carbon contacts CR, worked by an automatic Thury regulator R, which starts, stops, and reverses the motor MT as desired.

3. An adjustable resistance RA, permitting a modification of the current on the furnace, for instance, from 2000 to 10,000 amperes, by steps of 1000 amperes.

4. A controller CM for hand and automatic control.

5. A current transformer T, operating the solenoid of the regulator.

One cycle of operation in this system would be as follows:

We will suppose that the current flowing through the secondary bars to the furnace is above the normal. The current flowing from the secondaries of the transformer T to the solenoid of the regulator, will also be above normal, and the increased magnetic force will push the movable coil against the pull of the spring until the knife C will encounter the tappet K, pushing the latter out of its position, thereby releasing the pawl I. This pawl falls into the notch in the tappet wheel H which in turn brings the copper contacts Z on the lever, in contact with the carbon contacts, and the current immediately flows to the winch motor through the controller CM. When the current on the furnace has been brought back to its normal value, the regulator will cease to act and the lever carrying the copper contacts will remain in its central position, until again called upon to act, through a variation of current in the furnace.

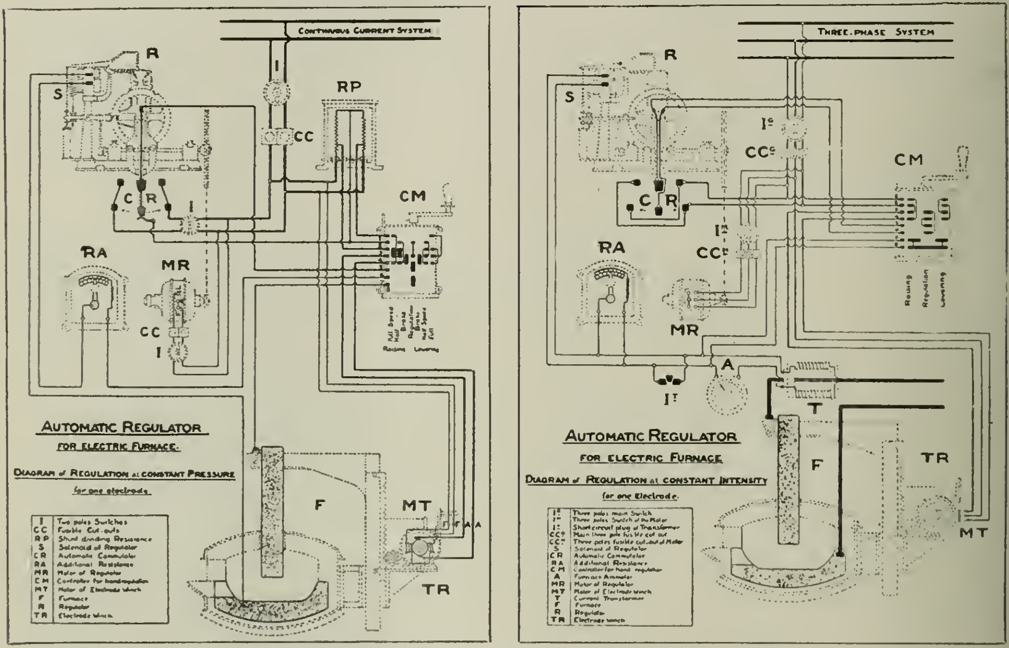

FIG. 2—AUTOMATIC REGULATOR SYSTEM FOR ELECTRIC FURNACES

---

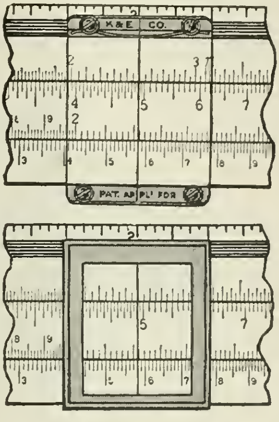
**The mineral output of California** for the years 1905 and 1912, with comparative estimate for 1913, is shown in the table below, compiled by F. McN. Hamilton, State Mineralogist:

| Substance | 1905 | 1912 | 1913 |
|---|---|---|---|
| Petroleum | $9,007,820 | $41,868,344 | $46,000,000 |
| Gold | 19,197,043 | 19,713,478 | 20,000,000 |
| Cement | 1,791,916 | 6,074,661 | 8,000,000 |
| Copper | 2,650,605 | 5,638,049 | 5,500,000 |
| Crushed rock and granite | 2,070,607 | 5,473,928 | 6,000,000 |
| Brick | 2,273,786 | 2,940,290 | 3,000,000 |
| Borax | 1,019,158 | 1,122,713 | 1,250,000 |
| Natural gas | 102,479 | 940,076 | 1,250,000 |
| Silver | 678,494 | 799,584 | 800,000 |
| Quicksilver | 886,081 | 866,024 | 700,000 |
| Other minerals including asphalt, clay, lead, marble, mineral earths, salt, tungsten, zinc, etc. | 3,391,238 | 6,035,238 | 7,500,000 |
| Totals | $43,069,227 | $91,472,385 | $100,000,000 |

## The Latest Slide Rule Improvement

A new patented indicator or runner for slide rules, called the "frameless," has just been perfected by Keuffel & Esser Company. Every figure on the rule is clearly visible at all times, there being no side pieces to the metal holder of the glass indicator, and therefore, nothing to hide any of the figures on the rule (see Fig. 1). This is one of the most important improvements in slide rules.

Many times, after setting the old-style indicator or runner, the user would find that he could not read the result because important figures were hidden by the frame or holder of the glass (Fig. 2). Frequently two, and sometimes, four or even six, eight or nine figures would be thus hidden; causing more or less inconvenience and uncertainty in reading the slide rule. The new "frameless" indicator or runner entirely obviates this difficulty.



FIGS. 1 AND 2—SLIDE-RULE INDICATOR—NEW STYLE, UPPER PICTURE; OLD STYLE, LOWER PICTURE

Thousands of engineers and scientists in every profession and industry, as well as contractors, builders, architects and merchants have found the slide rule invaluable as a time and brain saver in quickly and accurately making a great variety of calculations. In its various forms, it has been adapted by Keuffel & Esser Company to the needs of practically every line of work, including all branches of engineering, as well as chemistry. A new slide rule, especially adapted to the needs of the chemist, was described in our March issue, page 201.

## Compressing Air and Gases

One matter more than anything else has held back the introduction of compressed air for many industrial purposes. This has been the cost of compressing the air. The first cost of the compressor itself is high. Moreover, expensive foundations must be installed. Then the compressor and the receiver occupy much valuable floor space. The services of an experienced engineer are required to operate it. Taking all this together, it is clear that the overhead expense is a big item and becomes especially serious where the air is only required intermittently. Further, the power is an important consideration. All this explains why managers of industrial plants have been hesitating to introduce compressed air for purposes for which it would have been otherwise very useful.

A decisive advance has been made by the Nash Engineering Company, of South Norwalk, Conn., in the design of the Nash hydroturbine. These pumps are capable of delivering air or gas at 15 lb. pressure on continuous twenty-four-hour service with absolute reliability and high efficiency and it would seem that the Nash hydroturbine, because of its simplicity, low first cost, and low installation expense, small space occupied, absolute reliability and high efficiency, opens up a large field for the use of compressed air.

There is no longer any necessity of having long lines of air piping, with big losses due to leakage and air friction. A small Nash compressor, belted off a line shaft or direct connected to an electric motor can be located at the place the air is used, and started up by the operator of the machine when wanted.

Heretofore it has been the usual practice, where some of the work required high-pressure air, to install a compressor giving a pressure of 60 to 100 lb. and reduce the air needed at low pressure by throttling or by means of a reducing valve. Oftentimes 75 per cent of the work in the plant can be handled with entire satisfaction with a pressure not exceeding 10 to 15 lb. It is needless to say that there is no economy in compressing air to 100 lb. and then reducing it to 15 lb. for use.

The Nash hydroturbine offers a practical solution of this problem. A hydroturbine is installed of a capacity sufficient for the entire plant for both high and low-pressure air. This pump is arranged to maintain a pressure of 10 to 15 lb., depending upon the pressure required for the bulk of the work in the plant. If some air is required at 60 to 100 lb., a small compressor is installed, taking its air from the delivery side of the Nash hydroturbine and boosting it to the desired pressure. The compressor for the high-pressure air will be small, only one-half to one-eighth the size that would otherwise be necessary, the size depending on the amount of high-pressure air required.

The space occupied will be less. There will also be a saving in power, both for the high-pressure air, as well as the low-pressure air, because the Nash hydroturbine is very efficient. The air is used at the pressure to which it is compressed, and two-stage compression is used for the high-pressure air. The compression in the Nash is isothermal, therefore no intercooler is required.

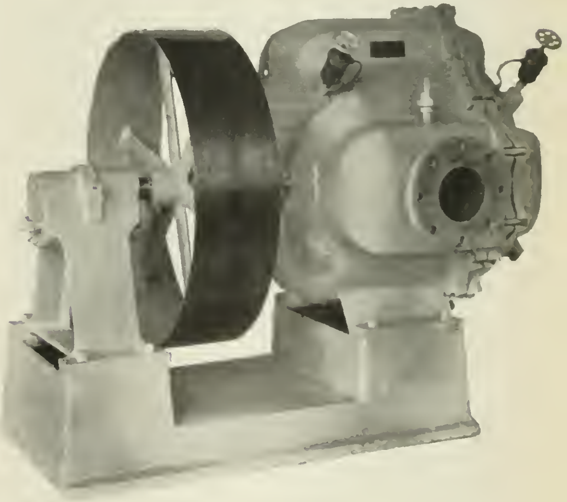


FIG. 1—HYDROTURBINE

The Nash Engineering Company, the exclusive manufacturers of air compressors and vacuum pumps working on the hydroturbine principle, have been building these pumps for about four years. Fig. 1 shows the latest single-stage design of their hydroturbine. It differs from the first pumps put on the market only in minor details, such as the additional outboard bearing, position of the outlet and inlet piping, etc.

The extreme simplicity of the pump is best illustrated by Fig. 2, wherein all the principal parts are shown. The case, head and wheel constitute the pump.

Fig. 3 is a cross-section showing the principle of operation. The pump consists of a casing and a head, surrounding a wheel with projecting blades, which is rigidly mounted on a shaft, supported by bearings in the head and casing. The casing is elliptical in section. The rotor, the periphery of which is a true circle, clears the short diameter of the elliptical casing by 1-16 in. to 3/32 in., depending upon the size of the pump, so that there is no possibility of the blades striking, even if the bearings become worn.

Above and below the narrow part of the ellipse, ports are cut through the casing, and similar ports are cut through the head, exactly opposite. These communicate with cored passages, connected to the inlet and outlet pipes.

Water, or other liquid, is introduced into the pump. The rotor is revolved by power applied to the shaft, carrying the water with it. The water, however, follows the casing due to centrifugal force.

This means that twice in a revolution it recedes from and surges back into the rotor, due to the elliptical form of the case. As the water goes out of the rotor it draws air in through the ports to fill its place. This air is carried around with the rotor, and is compressed and delivered through the outlet ports by the re-entering water. Each half of this elliptical case is really a separate pump. As the outlet and inlet ports are diametrically opposite, the pressures on the rotor, due to compression, are exactly balanced, thus relieving the bearings of all side-pressure.

Since the blades of the rotor are passing the outlet ports continuously, the air is delivered without pulsation.

The blades of the rotor are reinforced by two shrouds, as will be seen in Fig. 2, leaving just enough space between the hub to register with the ports. The steel shaft is a drive fit in the rotor, and is fastened securely by two pins going clear through the interior hub and shaft.

The shaft is supported by three bearings, one each in the head and casing, and one forming the outboard bearing. The pump and outboard bearings are dowelled to the case, and the head flange is recessed and fitted to the casing, so that exact alignment will be preserved if the pump is taken apart and reassembled.

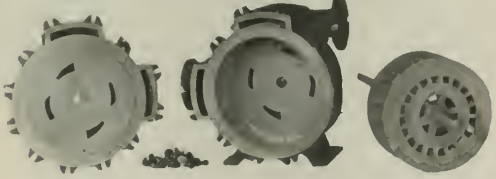

FIG. 2—CONSTRUCTION OF HYDROTURBINE

The bearing bushings are made of best grade of babbitt, containing about 85 per cent. tin. They are fitted so that they can be tapped in with a light mallet, and are prevented from turning by means of a lug cast in the bushing, which fits in a recess in the containing casting.

The outboard bearing is ring-oiled. The bearings in the head and casing are lubricated with graphite grease, as this is more reliable than oil in the presence of water. The grease is fed to the bearings by means of compression cups of special design, located near the top of the pump. The air pressure is admitted to the top of these cups to balance the pressure, so that the grease will flow to the bearings readily.

The outlet and inlet pipes are equipped with standard flanges. The design is such that the head can be removed and the rotor taken out without disturbing the piping.

All parts of the pump are made absolutely interchangeable.

It is apparent from the above that there is nothing about these pumps to get out of order. In fact, they are practically indestructible with any reasonable care. In addition to being absolutely reliable, they are very efficient, occupying small space, and are quiet in operation. They are so simple that anybody can operate them. All that is necessary is to keep them supplied with lubricant.

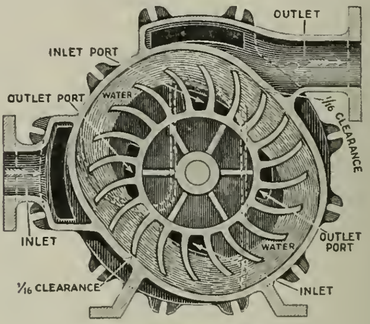

FIG. 3—PRINCIPLE OF OPERATION OF HYDROTURBINE

The standard pumps such as used for compressing air are made of cast iron. Where mild acid gas is to be handled, sufficient protection can be secured by keeping the contained water slightly alkali. Where the particular conditions of the plant would result in the corrosion of the cast iron the pumps are made of any other suitable metal or alloy.

While we have described in the above the use of the Nash hydroturbine for compressing air or gases it may be added that it is also a powerful and efficient vacuum pump.

---

**Monel metal**, the natural copper-nickel alloy, is finding a wide variety of uses, among which is the manufacture of non-corrodible window screen cloth.

**American Ingot Iron in England.**—The American Rolling Mill Company of Middletown and Zanesville, manufacturers of American ingot iron, have invaded England by closing up two contracts under which the Shelton Iron, Steel & Coal Company, of Stoke-on-Trent, and Richard Johnson & Nephew, Ltd., of Manchester, secure the right of using the American Rolling Mill Company's method. The capacity of the American works of the latter company has increased from 40,000 tons of sheet in 1906 to 166,000 tons at present.

**Large Metal Value in Utah.**—The value of the mine output of gold, silver, copper, lead and zinc in Utah in 1913 was $44,858,210, compared with $42,922,302 in 1912, according to Victor C. Heikes, of the United States Geological Survey. The production of gold was valued at $3,565,229, a decrease of $700,622, or 16.42 per cent, compared with 1912. The largest producer of gold was Salt Lake County, which yielded $1,777,214, against $1,788,730 in 1912. The West Mountain or Bingham district, in Salt Lake County, produced $1,774,815, or 49.78 per cent of the total output. The Tintic district, in Juab and Utah Counties, ranked first in gold output in 1912, but was second in 1913, with $1,412,462, or 39.61 per cent of the total.

## Prospects of Electric Zinc Smelting in British Columbia

From the *Daily News* of Nelson, B. C., we learn that there is an excellent chance of the Johnson electric zinc furnace being tried out on a commercial scale in Nelson or Trail, British Columbia. As the Johnson furnace and process are so well known to our readers, we simply report that a party consisting of Messrs. Byron E. Eldred, W. McA. Johnson and James Struthers, all of New York, and A. E. Barlow, of Montreal, visited Nelson and Trail on May 4, 5, 6 and looked carefully over the ground.

The plan is for the erection of a ten-ton furnace plant at a cost of $75,000, and the Nelson Board of Trade passed unanimously a resolution:

"That the Board favor and support the proposal that a grant be made by the Dominion government to the Johnson Electric Smelting, Inc., of $25,000 on completion by them of a demonstration plant of 10-ton capacity in West Kootenay ready for operation, and a second government grant of $25,000 upon a successful commercial demonstration of the operation of same by a continuous thirty-day run under the oversight and to the satisfaction of a representative of the government."

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

*Electroplating* (Continued)

175,134, March 21, 1876, Charles S. Minchew, of Taunton, Mass., assignor to Reed & Barton, of same place.

Relates to electroplating, especially upon soft metals, such as britannia ware, with other metals, and calls the process "impulsio-plating." The article is first made chemically clean by boiling in caustic alkali, then mechanically cleaned with sand, brushes and water. It is then wired in running water. It is then connected as cathode in a hot alkaline solution of oxalate of soda and a strong current passed. It is then quickly transferred to the plating-bath and the desired deposit made in a hot solution under pneumatic pressure. After the deposit, the article is washed and dried, and then subjected to a temperature of 180 deg. F., which is said to "drive in" the deposit.

215,463, May 20, 1879, Nathaniel S. Keith, of Brooklyn, N. Y.

Relates to the electrolysis of lead and increases the conductivity of the electrolytes by adding to solutions of lead salts, similar salts of more electropositive metals, such as of sodium, magnesium, aluminium, etc. The more nearly saturated, the higher is the conductivity.

273,467, March 6, 1883, Alexander Classen, of Aachen, Germany.

Relates to electroplating from solutions of oxalates, which are made as follows: to solutions of chlorides or sulphates of the metals to be plated are added solutions of potassium or ammonium oxalate to form double salts; ammonium oxalate is then added in excess to the hot solution, and later a small quantity of sodium carbonate may be added. For nickel, the following proportions are given: five hundred grams nickel sulphate and eight hundred grams of ammonium oxalate are dissolved in ten liters of water. The deposit is made from a heated solution, using an anode of carbon or platinum.

300,035, June 10, 1884, William Henry Walenn, of Islington, county of Middlesex, England.

Relates to electroplating copper, etc., at temperatures near the boiling-points of the solutions, in closed vessels, the solution being under pressure of about one atmosphere, or less. For copper, an electrolyte is made as follows: thirty-two ounces, avoirdupois, of cyanide of potassium, and one ounce of neutral tartrate of ammonium are dissolved and diluted to one imperial gallon. The solution is then charged with copper from an anode until about three ounces per gallon is dissolved, using a large anode and small cathode. To this solution is added ammonia cupric oxide, until the solution turns slightly green in color. The ammonia cupric oxide is made by adding caustic potash to copper sulphate, boiling the solution, removing the precipitate and dissolving it in strong ammonia water of 0.880 specific gravity, to saturation. The deposits of copper are said to be adhesive and ductile, and not to separate when the plated sheets are hammered, etc.

330,149, November 10, 1885, Gaston Pilet and Clément Carry, of Besançon, France.

Relates to electroplating palladium, and describes an electrolyte made of chloride of palladium containing ten grams of metal; five liters of water; one hundred grams of phosphate of ammonium; five hundred grams of phosphate of sodium; ten grams of benzoic acid, which may be omitted, but is said to bleach the deposit, and renders the deposit more striking upon iron or steel. The bath may be used cold to produce a steel color deposit; if heated to from 40 deg. C.-50 deg. C., the color is whiter. A feeble current is preferred. Another electrolyte is also described.

331,104, November 24, 1885, William H. Winslow, of Brooklyn, N. Y.

Relates to electroplating articles with iron, and then converting the iron coating into magnetic oxide. An electrolyte containing twenty parts of salammoniac to one hundred parts of water is electrolyzed with two wrought iron plates for anode and cathode. After the electrolyte is suitably charged with iron, the cathode is removed and the article to be plated inserted. The plating must be carefully conducted; about one hour's time being considered sufficient. The iron-coated article is then removed and heated in an atmosphere of superheated steam in a muffle at about 1000 deg. F. to 1200 deg. F. for from five to seven minutes, which converts the iron coating into magnetic oxide. It is said to have a steel-bluish-black color, hard, non-corrosive and very attractive in appearance. Refers to a copending application which became patent No. 331,105.

331,105, November 24, 1885, William H. Winslow.

Relates to articles having a coating of magnetic oxide of iron, produced by the process described in his copending application which became patent No. 331,104. The patent describes the production of an electrotype having a magnetic oxide of iron printing face.

## Personal

Mr. Lawrence Addicks has resigned as superintendent of the Chrome, N. J., refinery of the U. S. Metals Refining Company, and is now in Douglas, Ariz., in an advisory capacity, to study the possibilities of leaching at the various Phelps Dodge properties and direct the large-scale experiments under way at present at Douglas.

Mr. E. L. Messler, formerly with the Jones & Laughlin Steel Company, as general superintendent of their Pittsburgh coke ovens, blast furnaces and ingot mold foundry, and for the past two years as assistant to the president of Riter-Conley Manufacturing Company, is no longer associated with the latter firm He has as yet not decided what line of work he will follow. Mr. Messler's present address is care of the Duquesne Club, Pittsburgh, Pa.

**Mr. William P. Baer**, formerly of the Sprague Electric Works of the General Electric Company, has joined the forces of the Trumbull Electric Mfg. Co., and will represent them in part of the Middle West and also a part of the Southern territory.

**Mr. George H. Garrey** has severed his connection with the American Smelting & Refining Co., and allied companies, as their chief geologist, and has opened an office as consulting mining geologist and engineer at 115 Broadway, New York.

**Mr. W. R. Hulbert**, of the Goldschmidt Thermit Company of New York, presented recently a fascinating lecture on thermit and its latest developments in railway shop practice before the Railway Club of Pittsburgh. The paper is printed with illustrations, together with the extended discussion which followed, in Vol. 13, No. 3, of the official *Proceedings* of the Railway Club of Pittsburgh.

**Mr. Henry E. Jacoby** announces the removal on May 1 of his offices to larger and more spacious quarters at 95 and 97 Liberty Street, where he will continue to specialize on chemical machinery and equipment of all kinds, including a much larger and more improved line of vacuum drying apparatus.

**Mr. J. B. Mendenhall**, formerly with the National Lead Company, is now southern representative of the Great Western Smelting & Refining Company.

**Mr. J. Malcolm Muir**, business manager of *Metallurgical and Chemical Engineering*, was married on May 14th to Miss **Lida C. Kelly** in Louisville, Ky. Mr. and Mrs. Muir are now enjoying a honeymoon in the sunny South, somewhere in the Blue Ridge Mountains.

**Dr. Joseph Struthers**, formerly secretary of the American Institute of Mining Engineers and editor of Mineral Industry, has accepted the office of second vice-president of the Johnson Electric Smelting, Inc., controlling the American rights of the Johnson electrothermic process for the treatment of zinc ores and zinciferous lead and copper ores, with offices at 18 East Forty-first Street, New York City.

**Mr. W. P. Thornton**, who has been with the Riter-Conley Mfg. Co. for many years in various capacities, has resigned to accept a position with the Treadwell Construction Co. During the erection of the eight Gary blast furnaces of the United States Steel Corporation he was the engineer in charge for the Riter-Conley Company.

**Mr. Alois von Isakovics**, of Monticello, N. Y., lectured on May 8 before the Institute of Arts and Sciences and the Senior Organic Students of Columbia University on "perfumes and flavors, their chemistry, synthesis and practical application." He was introduced by Professor M. T. Bogert and after the lecture a vote of thanks was extended to Mr. von Isakovics on motion of Dr. C. F. Chandler.

## Obituary

**Herman Frasch** died on May 1 at his home in Paris at the age of sixty-two. Herman Frasch was born in a small town near Stuttgart, Wuerttemberg, the son of the burgomaster of the town. Leaving the gymnasium at Halle, at the age of sixteen, he apprenticed himself for a time to a pharmacist. He came to the United States in 1868 and found his first employment in the laboratory of Prof. John M. Maisch at the Philadelphia College of Pharmacy. A little later he established a laboratory of his own, in which he made his first invention of importance, completed in 1876 a new process for refining paraffin wax. This he sold to a subsidiary of the Standard Oil Company. In 1885 he bought an oil field in Canada, started the Empire Oil Company, and soon invented the process for eliminating the sulphur which before that time had prevented the use of the oil for illuminating purposes. This invention was purchased by the Standard Oil Company, whose chief chemist Frasch then became. After serving as chief chemist of the Standard Oil Company for over twenty years, Frasch turned his attention to extracting sulphur from the beds underneath the marshes of Louisiana. This was accomplished by sinking shafts down to the bed through which the sulphur was melted by superheated steam and forced up by the pressure generated. This novel industry is in the hands of the Union Sulphur Company, of which Frasch was president. In 1912 the Perkin Medal was awarded to Herman Frasch by the Perkin Medal Committee, consisting of representatives of the Society of Chemical Industry, the American Chemical Society and the American Electrochemical Society. A report of the proceedings at the presentations of the Perkin Medal to Herman Frasch will be found in our issue of February, 1912, which contains a full account of his life and his lifework.

* * *

Dr. Walter Feld, a prominent German gas engineer, died on March 15th. Among his most notable inventions is a centrifugal gas washer for the purification and cooling of blast-furnace and producer gases, for the recovery of metal dust from gases of lead and copper smelting plants, for the extraction of tar from coke-oven gases, etc. A very interesting new process of Dr. Feld relates to the extraction of ammonia and hydrogen sulphide from coal gases and the direct production of ammonium sulphate therefrom without the use of sulphuric acid. Two interesting articles by Dr. Feld on these subjects appeared on pages 395 and 436 of our volume X (1912).

## Book Review

**The Copper Handbook.** A Manual of the Copper Mining Industry of the World. By **Walter Harvey Weed.** Vol. XI., 1912-13. Price $5. Houghton, Mich.: Walter Harvey Weed, 1914.

Under the able editorship of Horace Jared Stevens, the Copper Handbook had grown from a modest book of 300 pages, covering Michigan mines, till the tenth edition (1910-11) had become a manual of the copper industry of the world and a volume of 1902 pages. It had become recognized authority and its account of the doings of the copper mining companies was accepted as impartial and fearless when Stevens died on April 12, 1912.

Fortunately his untimely death did not mean the end of the Copper Handbook. It was acquired by Mr. Walter Harvey Weed a year after Stevens' death and the eleventh volume has just been issued. It may be said to be fully up to the standard set by its founder.

The first part (989 pages) gives detailed notes on all copper mines in North America, alphabetically arranged, and is followed in the second part (39 pages) by a very useful geographical index in which the mines are grouped by countries, states, counties, and mining districts. Part III. (285 pages) gives detailed notes on foreign companies. Part IV. (47 pages) contains statistics and part V. (53 pages) a list of dead mining companies.

"As in former editions, any gold, silver and lead mines producing copper as a byproduct has been included, practically making the book a mining manual, at least for America." As a reference book, in the arrangement of its contents, the present volume shows considerable improvement over former editions.

## The First Chandler Lecture

The celebration of the fiftieth anniversary of the Columbia School of Mines was the occasion of a wonderful outpour of love and affection for its only surviving founder, the dean of chemistry in America, Dr. Charles F. Chandler. It was the psychological moment for the fitting inauguration of the lectureship which is to commemorate forever Chandler's name at Columbia. And as Dr. Baekeland was the lecturer, it goes without saying that the first Chandler lecture was brilliant and worthy of the occasion.

Under these conditions our apologies would be due to our readers for not publishing in full Dr. Baekeland's lecture in this issue, if it was not for a remarkable clause in the Chandler Foundation to the effect that the Chandler lecture is first to be published in the official "Quarterly" of the School of Mines, which may mean a delay of a month or two. Of course, such a clause, like any attempt to put a release date on any speech made in public, is absurd. It can be legally enforced only if the Chandler lectures are to be star chamber proceedings. Is this the intention? Or is it a suggestion that watchful waiting is a good preparation for prospective readers of Chandler lectures? Or it is an attempt to cripple live technical newspapers in favor of their slower brethren? We can't conceive of any sensible reason, if widest publicity is really desired for the Chandler lectures. Or is the reason psychological? Was it simply a case of Homer nodding?

## The Cost of Noise

In a recent conversation the superintendent of a large stamp mill made the observation that "noise costs money." We had been discussing the use of stamps as crushing machines and the comparative merits of various devices for crushing ore. One of the arguments advanced by this superintendent against the use of stamps was the tremendous and never ending noise produced by the falling weights. In his opinion the din was responsible for many misunderstood directions and orders to employees, resulting in confusion, loss of time, and expensive mistakes. The point is readily perceived. The average mill employee is anxious to give the impression that he understands the boss's orders, and rather than ask a question for further information he will sometimes pretend to understand and then go and seek advice from a fellow workman. The order may be wrongly executed or not at all. The noise of the stamps contributes greatly to this condition, makes it difficult to give and receive orders, and undoubtedly causes many mistakes. The cost of noise may not be estimated exactly, but it is a real factor.

## Welfare Work in the Steel Industry

Eleven years ago, when the annual scale settlement was made between the Amalgamated Association of Iron, Steel and Tin Workers and the union tin plate mills, the only change made in the scale was the adoption of the following paragraph: "That the company furnish ice or well water to its employees." Considering the nature of the work at the hot mills the demand of the men, thus complied with, was certainly a very modest one.

The incident gives us a viewpoint. When barely over a decade ago it required the demand of a fairly strong labor organization to secure suitable drinking water for men whose occupation required them in summer to drink water not by the quart but by the gallon per turn, it is doubtful whether we are able, without such checks, to realize the sweeping character of the welfare work which has been in progress in recent years in the steel industry.

Again, if we do realize the extent of the work which is going on there is a possibility of misjudging the influences which cause it. Our London contemporary, the *Iron and Coal Trades Review*, for instance, with what is almost a covert sneer, suggests that the United States Steel Corporation, recognized as the greatest leader in this work, is defending a suit by the government for its dissolution under the Sherman anti-trust law. Who could prove his ground for an assertion that it is because the Steel Corporation has been under fire that it has undertaken these things? That it is because the corporation is very large that it has done so much is, on the other hand, a statement which can be supported by much circumstantial evidence. Among the "independent" steel manufacturers, for instance, it is commonly found that the larger the concern, the more welfare work has been done. There is ground, in the existing facts, for formulating a general principle that the larger the manufacturing interest the more likely it is to adopt comprehensive plans for improving the working and home conditions of its employees. The work has been principally of a pioneer nature and large interests are more able to do such work than small interests. When practices have become well established the difficulties in the way of the smaller interests are removed.

Welfare work, including mill sanitation, establishment of hospital departments, beautifying mill surroundings, provision of rest places, protection against accidents, playgrounds for employees' children, encouragement of home gardening and the like, are already yielding tangible and direct results. There is no question that "they pay." There is little danger of making mistakes. The various efforts that have been put forth have almost invariably been strikingly successful, and this is a greater proof of the propriety of the work than is generally recognized.

Compare, if one will, the failure of so many systems of profit sharing. Welfare work as we know it is much less than a decade old. Profit sharing is many decades old, and yet with all the experience gained the failures have been so many that the question may well be raised to-day whether there is any known system of profit sharing which can be guaranteed to give adequate results.

Certainly there are very recent instances of absurdly inadvisable methods, the most glaring doubtless being that of the famous "car" builder of Detroit. It is the greatest possible tribute to welfare work that it has been so signally successful in its very earliest years when after decades of experiments so theoretically desirable a principle as profit sharing cannot yet be carried out with anything like similar success.

## Industrial Peace and Professional Ethics

The last graduating class of the Colorado School of Mines was honored at the commencement exercises by an address from Dr. Rossiter W. Raymond, whose subject was "Professional Ethics." Filled with excellent advice on a phase of professional life too often neglected, the address came as a fitting close to four years of absorbing application to technical studies, as well as a practical introduction to an honorable engineering career.

The ethical principles of life are simple in formula, and well known to all educated men; but their consistent application to life seems difficult on account of the complexity and multiplicity of human relations. Thus, unless studiously avoided, morality among men may come to be a relative matter of training, experience and interpretation of principles, often leading to perverted reasoning and resulting in the acceptance of misleading half-truths, such as "the end justifies the means." Comparing man's relations in war and peace, Dr. Raymond finds that the recognized elements of warfare have been adopted in business. Speaking of war he says that "perhaps its greatest evil result is its corruption of the ways and habits of peace." Certainly industrial peace is coming to be recognized as a desideratum far above the success that is coincident with, and dependent upon, acts of warfare and piracy in business. Hence the need for "honesty, justice and fair play," which are accepted among us as the principles of ethics.

Touching directly on the ethics of engineers, chemists, and metallurgists, Dr. Raymond outlined some of the obligations which are imposed on men in those professions: as authors, as employees, as factors in business transactions and as advisors.

The ethics of authorship, either of reports or papers, demand that the writer shall not pretend to knowledge that he does not possess or ability that he has not acquired. Authorship implies a contract on the part of the writer to present clearly and logically to the mind of the reader those things to which he makes legitimate pretense of knowledge. He is not justified in creating a false impression to gain personal ends, nor in appropriating as his own the language of others.

As an employee an engineer must possess and display the quality of loyalty as well as ability. This is "dictated by honor, and even by selfish interest." How rare is the employee who shows the same devotion to his work that is felt by his employer. Ability counts for little in personal equipment if it is not supported by loyal devotion. "The time is past when the master could watch all the details"; and with the development of vast enterprises involving the co-operation of many men, the demand for loyalty is greater than ever before.

As a business agent the engineer must act in perfect faith and maintain his integrity unquestioned. The secret commission on purchase of property or equipment is one of the most insidious forms of temptation to forget or neglect the interest of a client. Secret acts sooner or later come to light, and usually at a time when explanations are difficult or impossible.

In advising clients on professional matters the engineer must be free to tell the whole truth, not suppressing any pertinent facts. His reports should be made in such a manner that they cannot be misconstrued or garbled by unscrupulous persons. In giving expert testimony in litigation he should not take the witness stand unless he has examined the case and believes that he can be of service to his client; nor should he serve his client for money to the detriment of his own good name and reputation.

The spirit of the time demands fair play and a square deal. The engineer must be frank, open and above board in all his dealings, and must preserve his integrity by avoiding complications that may arise from the disclosure of secret acts. With the speaker at Golden we may say, "Do not do what you could not tell without shame," and likewise ask, "Why not walk in the light?"

## Craft, Cunning, and Intelligence

Words like metals have varying uses. Meanings like metals are of different degrees of purity. It can be laid down as an axiom that the word intelligence has the meaning in its broadest sense that connotes the ability to see and remember things with the result of being able to accurately foresee the future. If one will examine life and foresee the common use of the word "intelligence" he will see that people usually mean just about that and nothing more, the ability to foresee the future, even though the future may be immediate. For instance, if a man were walking by an office building where a safe was being hoisted up and he crossed to the other side of the street we would call him cautious or prudent, but we would basically mean that he was intelligent. Man is a sentient creature, but he is distinguished from other creatures also sentient, such as animals because he has intelligence and it is by use of intelligence that he has arisen from savagery and has conquered nature.

The word intelligence can be used in a concrete sense or it can be used in an abstract sense. We can look to the effects of intelligence to understand it or we can understand it directly by subjective powers.

Probably all the ills of individual and state are caused by a lack of full intelligence. And in a narrower sense intelligence of the higher type can be differentiated from intelligence of a lower type, i.e craft or cunning. Craft is a word originally used objectively to denote the power of "doing something." Cunning derived from anglo-saxon word cognate with "can," likewise means ability "to do something."

Nowadays both these words—craft and cunning—suggest the ability "to do somebody." So it is in the disinclination of people to see the practical and efficacious difference between intelligence and craft that is the cause of what can be vaguely described as vague social unrest. It is plain that if the public frowned on or ostracised men that wrecked railroads to amass money by craft and cunning such men would cease to exist. But the public has had always a sneaking admiration for such men. The public kicks at the trusts, but in the past fifteen years have given ear with eagerness to the accounts in magazines and newspapers of the intimate life and pursuit of happiness of the individuals who have grown rich out of the trusts. It would seem to follow that the public is to blame in this respect and did not really know itself.

The word intelligence, however, has a broader, higher and nobler application. A man who grows rich by building up a railroad, does good rather than harm and he has gained his power by true intelligence, rather than by craft or cunning. The three words, craft, cunning and intelligence, have also a social application. Intelligence operates to benefit society, craft to hurt it. Intelligence sees clearly and works for its own good in part, but in larger part for the good of the community. It attains its unselfish ends, possibly with a selfish motive, but at least with altruistic effects. Craft or cunning simply looks to its own immediate good. By their fruits we must know them.

For instance, a rat is foxy because it escapes the trap and "gets away" with the cheese and a fox is ratty because it steals a chicken without being caught. From its own standpoint, a rat and a fox are eminently intelligent and unqualifiedly respectable—does not a rat wear dignified side whiskers and does not a fox brush himself daily?—but from the standpoint of man they are asocial agents and anti-social. Accordingly a foxy business man or a ratty politician—oily, slick articles—are asocial because each merely thinks of himself from the viewpoint of society each is not intelligent but cunning. It all depends on the viewpoint.

Now, if society could and would discriminate between intelligence on one side and craft or cunning on the other side, if the rewards were given for real work, not for results of "getting by" or "getting away with it" or "slipping something over," expressions of the vernacular so suspiciously frequent as to almost postulate their universal acceptance as true doctrine—we would have fewer lawyers and more good ones, real leaders of religious thought rather than ecclesiastical charlatans, statesmen—not mere politicians or demagogues, fewer militant suffragettes and more pleasing women, happy tillers of the soil instead of bad farmers, and the cost of living would go down.

## Rapid Evaporation of Solution in the Determination of Silica and Alumina in Iron Ores

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In the estimation of silica and alumina by the method of fusion with sodium carbonate, every chemist is confronted with the problem of evaporating the solution in the shortest possible time. The water-bath is practically excluded on account of the long time required, and the operation usually is conducted in an evaporating dish placed directly on the hot-plate and covered with a large watch-glass. The drawbacks to this procedure are evident to all who have to do such work; there is too great a risk of loss by bumping, spattering, and overheating.

In order to obviate these difficulties, the writer has made use of the following device which has proved very satisfactory. Make a ring of sheet tin, $\frac{3}{4}$ in. high and $4\frac{3}{8}$ in. in diameter. This is suitable for use with an evaporating dish $5\frac{1}{2}$ in. in diameter; other dimensions can be used for dishes of various sizes. The ring is placed directly on the hot-plate and used as a support for the evaporating dish. No cover is required. With a ring and dish of dimensions given above, the bottom of the dish will not touch the hot-plate, and we have, in effect a hot-air bath on which evaporation will proceed under the boiling point of the solution. All of the vapors can escape readily, not being retained by or condensed on a watch-glass cover.

While the evaporation is proceeding the operator is at liberty to dispose of his time as desired until a point is reached where the residue appears just moist or damp. The dish should then be removed to a cooler place to prevent any loss by decrepitation of the chlorides, but as soon as no more vapors escape and the residue appears dry, it is safe to complete the dehydration on the hottest spot of the plate.

The advantages accruing to this method of evaporation are: The dish is more easily handled and cools more quickly when removed from the plate; the residue appears more homogeneous; no crust has to be washed from a cover; less solution has to be filtered, and the volume of the filtrate for the final determination of alumina is small. The operation requires less time.

S. Wurzel.

Sunrise, Wyo.

## Is There a Complex Ore Problem?*

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—(1) Re: the "complex ore problem"; any ore is complex that will not show a profit when treated by the commonly known and developed metallurgical methods. All ores carry more than one possible value, and many a large number, and thus as industrial uses arise the complexity of commercially converting nature multiplies and the end is infinity.

(2) The presence of zinc "blende" in a form that is not amenable to mechanical separation is the usual reason for the word "complex." It most certainly is not the fault of the present methods in metallurgy or lack of skilled operators, but entirely the lack of commercial methods and application.

(3) In a broad sense we are not utilizing half the value that our non-complex ores show us because the balance is uncommercial under the imposed condition, while there are innumerable examples of very large tonnage carrying heavy gross values that are not treated because uncommercial. Value is a vague term to use, as it may be interpreted to mean the metal value of the ore as gross, or net, and again, might be figured as the value of compounds of metals or constituents manufactured directly from ores.

(4) As applied to present practised metallurgical methods the presence of zinc "blende" existing with other sulphide is the most usual refractory element, but baryta, arsenic, or even other elements might render the ore uncommercial or complex.

(5) There will be no universal process that will solve the complex ore problem because it is not a universal problem. Roasting and slag smelting has had its day, but will be limited to ores where heavy values are not carried off in slags. Electric smelting will supplant much present cupola and reverberatory practice.

Mechanical dressing will always pay up to a point where waste does not defeat it. Processes for preparing ores for the pyrometallurgical process, other than mechanical, will play a part. Leaching and chlorination processes are clearly the best methods in many instances. Volatilization methods as steps in complete treatments or direct treatment for commercial separation of values are sure to become very prominent. Electrometallurgy as applied in refining, distilling, producing reactions now impractical, will fill voids not now realized by many.

(6) Microscopic examination would belong to the laboratory department to determine the nature of the ore; the treatment used must be governed solely by the commercial aspects. There is rapidly coming a revolution in metallurgy due to technical education, and progress lies in the hands of the inventor or research agent coupled with financial support to commercialize his creation.

Brooklyn, N. Y.

## Definition of Alloys

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—In your April issue, page 218, you quoted the decision of His Honor, Judge Hough, in the suit on the Welsbach patent, No. 827,017, for a Cerium Pyrophoric alloy, and which decision contains the statement: "The important words (for this case) are *two or more metals*, and all the experts examined agree that an alloy must contain that number."

Since the well informed readers of your journal know this definition to be incorrect, allow me to state that the Court erred in stating that *all* of the experts thus incorrectly defined the scope of the term alloy. In my own expert deposition in this suit, when the definition quoted by the Court was called to my attention in Q. 40, I replied: "an alloy may be formed by combining or mixing a metal with some *non-metallic* solid elements so as to form a solid coherent product." And, as I stated in my answer to xQ. 42, my opinion was confirmed by one of the opposing experts, who also described "such a manner of making an alloy—a *pyrophoric* alloy—of *cerium* and silicon."

Chas. J. Thatcher.

New York City.

---

*Mr. Choate's interesting communication was received after the communications by Messrs. Clerc and Godshall and the editorial summary which will be found on page 471 of this issue, had already been set in type and arranged in page form. Mr Choate's communication is, therefore, printed separately at this place.—Editor.

## The Western Metallurgical Field

### Chlorination at Park City, Utah

The chlorination mill of the Mines Operating Co. at Park City Utah, has been running steadily for several months at a capacity of about 165 tons of ore per day. During March 5000 tons of ore were treated from which 7 tons of precipitate were produced for shipment. The plant is reported to be operating at a profit. Filling from the Ontario stopes is being treated. This ore contains 9 to 10 oz. silver and 0.03 oz. gold per ton, 0.05 per cent. copper, 1.0 per cent. lead and about 1.0 per cent. sulphur. With the ore crushed to $\frac{3}{8}$-in. size the saving is 80 per cent. of the silver, 90 per cent. of the copper and 30 per cent. of the gold. Some lead is also extracted but practically nothing is realized on it when shipped to the smelter. When crushing to 8-mesh, 90 per cent. of the silver can be saved.

This process consists essentially of crushing the ore to $\frac{3}{8}$-in. size, chloridizing-roasting with salt, leaching with acid and salt solution, and precipitating the silver, copper, gold and lead on scrap iron. The ore first passes through a trommel with 1-inch openings, the oversize going to a gyratory crusher and the undersize to a stationary dryer. Seven per cent. salt and 2.8 per cent. coal dust are then mixed with the ore by feeding these materials from their respective bins on to a common belt conveyor. The ore, salt and coal dust mixture is crushed in rolls to pass a $\frac{3}{8}$-in. trommel, and stored in bins over the roasters. Chloridizing-roasting is performed in 6 vertical blast-roasters, each of about 35 tons daily capacity. After roasting is completed, side doors at the base of a roaster are opened, and the hot ore is sluiced out of the furnace with weak, acid, mill-solution into a wooden leaching tank of which there are six. After settling for about 3 hours, the solution is drawn off through the bottom of the tank to the precipitation boxes. Barren solution is then turned on the tank for from 20 to 24 hours, passing to the weak solution tank for use in sluicing out the roasters. The tanks are then sluiced out with water. There are two series of precipitation boxes containing all kinds and grades of scrap iron. Silver is precipitated in the front boxes, followed by copper, with a predominance of lead in the last boxes. There is no marked dividing line in this precipitation as all the metals come down in all parts of the boxes, but there is sufficient distinction to be noted by the eye.

A novel feature of the plant is the type of roaster employed. It consists of a vertical shaft of square horizontal cross-section, with grate-bars in the bottom to support the ore, beneath which the air blast is introduced. The roasters are built of brick or concrete and lined with cement so as to give a smooth vertical wall. Wooden grate-bars are used, which are covered with about 4 in. of coarse and crushed ore to protect them from the heat. As they are wet by the solution in sluicing out the roaster and protected by the covering they have no great tendency to burn, especially with the blast driving the heat up and away from them.

The roaster is of intermittent operation as at present constructed. After a charge has been removed, the 4-in. covering over the wooden grates is stirred up by the laborers to prevent caking. A small amount of coal dust moistened with coal oil is then spread over the floor of the roaster. This is ignited, a little ore shoveled in through the side doors, and then after closing the doors the furnace is charged to a depth of about 6 feet with the ore, salt and coal dust mixture from the ore chutes above the furnace. Charging and roasting take about 16 hours and discharging or sluicing about 6 hours. An experimental 9-ton roaster has shown the possibility of modifying the furnace for continuous operation by the use of steel grates arranged so as to partly discharge the furnace when moved horizontally for a short distance. This roaster is always filled with ore. When the roast is complete, the grates are operated mechanically to lower the ore in the shaft about 18 in., when more of the mixture is charged at the top. Discharging in this manner is done about every $1\frac{1}{2}$ to 2 hours, taking not over 5 minutes. This furnace has considerably reduced the necessary labor.

The leaching solution used in this plant is barren mill solution from the precipitation boxes to which sulphuric acid is added in the barren solution tank. It contains from 3 to 4 per cent. of hydrochloric and sulphuric acids and as high as 20 per cent. salt. About 70 lb. of 60° B. sulphuric acid is added per 24 hours, or at the rate of about 0.42 lb. per ton of ore. Some bleaching powder is added in the leaching tanks, about 20 lb. per tank, to assist the solution of the gold. No difficulty has been experienced with fouling of solutions due to presence of iron. The solution does not contain over 2 to 3 per cent. iron. The precipitate from this solution contains 4,000 to 10,000 oz. silver and 1 to 5 oz. gold per ton, 30 to 40 per cent. copper and 10 to 25 per cent. lead. The scrap iron consumption is one ton of iron to a ton of precipitate.

The process employed at this mill appears to be working satisfactorily for the extraction of copper and silver from this low grade material. Wooden tanks and pipes, and air lifts are used for handling the acid solution. No more apparent difficulty is experienced with this solution than with ordinary cyanide solution. Wooden valves were used at first, but rubber hose and clamps are now installed and give better satisfaction. Materials are stated to cost laid down at the mill as follows: Coal dust, $1.75 per ton; salt, $4.45 per ton, and sulphuric acid, 1 cent per pound. As the smelter does not pay full value for the silver in the precipitate, a refinery would be added if a new plant were constructed. The silver and gold in solution would then be precipitated on copper, and the copper and lead on iron, thus producing a gold-silver bullion and blister copper.

### Company Reports

From the annual reports for 1913 of four of the large copper companies the following tabulation of data is prepared:

| | Chino | Ray | Nevada | Utah |
|---|---|---|---|---|
| Ore milled, tons...... | 1,942,700 | 2,365,296 | 3,139,137 | 7,519,392 |
| Copper content %.... | 2.033 | 1.719 | 1.599 | 1.247 |

The operation of the Chino plant during the last seven months of the year clearly demonstrated an average mill capacity in excess of 6,000 tons per day. No additions of consequence were made to the mill except in the coarse crushing plant, where another crusher and set of rolls were provided to insure against delays. The low ratio of concentration was due to the high iron content of ore from certain parts of the mine, resulting in an abnormally large tonnage of concentrates and an increased cost in transportation and smelting. The installation of a plant for recleaning concentrate has improved this condition.

All of the eight sections of the Ray Consolidated mill have been completed and are ready for operation as needed. Some important changes made in the flowsheet last year has enabled the management to increase the tonnage handled and at the same time improve the metallurgical results. The slightly increased cost of milling was due to intermittent operation during the progress of construction. There has been a marked decrease in accidents at mine and mill, which the company attributes to its "safety first" campaign. A school of instruction for the avoidance of accidents, mine rescue and first-aid work is maintained, and prizes are offered to employees suggesting the best safety appliances.

The increased cost of copper production at the Nevada Consolidated was due to the lower ratio of concentration which resulted in increased smelting cost. An increase in wages also added 0.394 cents per pound of copper produced. Replacements and betterments were responsible for an increase of 0.19 cents per pound of copper. Many improvements were made in the concentrator in 1913, resulting in improved settling of slime and recovery of water, improved concentration and classification. At the Steptoe smelter the roasting plant was enlarged by the addition of two furnaces. In the reverberatory department there has been an increase in capacity of furnaces from 262 tons charge in 1911 to 371 in 1912 and 481 in 1913. The longer furnaces have not shown a reduction in oil ratio but show better costs.

**The Utah Copper Co.** completed in 1913 the alterations in the coarse crushing departments at both the Magna and Arthur mills. During the year when running on low-grade ore, the Magna plant demonstrated its ability to handle nearly 14,000 tons daily, and the Arthur mill over 10,000 tons. This gives an aggregate capacity of 24,000 tons daily for very low-grade ore. With material of average grade the economic capacity of the mills is about 21,000 tons per day. A decreased percentage of recovery is noted, due to the lower average grade of ore treated. The total cost of mining, transportation and milling was but $0.9761.

From the seventh annual report of the **La Rose Consolidated Mines Co.**, Cobalt, Canada, we take the following data referring to operations for 1913. The company produces high-grade ore for direct shipment, and low-grade rock for concentration by the Northern Customs Concentrator.

SHIPMENTS

| | Dry tons | Oz. silver per ton | Per cent of total net value |
|---|---|---|---|
| Silver-Cobalt-nickel ore.... | 1,275.8 | 1,500.8 | 75.7 |
| Low-grade silicious ore.... | 1,076.5 | 112.5 | 3.4 |
| Nuggets .................. | 6.1 | 22,658.1 | 5.9 |
| Concentrates ............ | 915.9 | 456.6 | 15.0 |
| Totals and average...... | 3,274.3 | 791.8 | 100.0 |

COST OF PRODUCING SILVER

| | Per ton ore | Per oz. silver |
|---|---|---|
| Mine operation ............ | $117.23 | $0.1474 |
| Concentration ............. | 30.90 | .0388 |
| Marketing ores ............ | 48.96 | .0616 |
| Depreciation .............. | 3.57 | .0045 |
| Corporation and traveling.... | .66 | .0008 |
| | $201.32 | $0.2531 |
| Less rents, interest and discounts ............... | 19.96 | .0251 |
| Total cost production.... | $181.36 | $0.2280 |

Cost of production amounted to 38.62 per cent of gross value of ore produced.

CONCENTRATION

| | |
|---|---|
| Ore milled, tons.......................... | 37,556 |
| Silver content, oz. silver per ton............ | 13.53 |
| Concentrates produced, tons............... | 950.11 |
| Silver content, oz. silver per ton........... | 460 |
| Cost of milling, dollars per ton........... | 2.73 |
| Average tonnage for 313 days............ | 120 |
| Ratio of concentration.................. | 39.5 |

The picking and jigging plants at the mines produced 292,886 oz. silver in jig concentrates which was added to the high-grade ore. The rock on the dumps at mines amounts to 91,857 tons, estimated to contain about 15 oz. silver per ton.

**The Anaconda Copper Mining Co.** reports on its operations for 1913 as follows: Severe weather in January and February, 1913, caused a diminution in the quantity of ore treated, and this, combined with the necessity of a shut-down at the Washoe smelter in October for the purpose of cleaning flues, resulted in a lessened output of refined copper for the year, as well as an increased cost for the same. The company's mines produced 4,644,201 tons of ore and 7243 tons of precipitates. The reduction works treated 4,016,689 tons of ore and cupriferous material at Anaconda, and 1,170,150 tons at Great Falls. Production at these plants was as follows:

| | Copper, lb. | Silver, oz. | Gold, oz. |
|---|---|---|---|
| Anaconda ........ | 205,730,594 | 9,026,690 | 53,935 |
| Great Falls ...... | 64,571,050 | 1,294,606 | 10,964 |

The experimental work on slime concentration has been finished and plans have been adopted. Centrifugal concentration has been abandoned in favor of treatment on round tables. A plant of 2,000 tons daily capacity is under construction, comprising a slime dewatering plant of 160 Dorr thickeners, a round-table plant of twenty round tables of twenty decks each, and a concentrate dewatering plant of five Dorr thickeners. It is expected that this equipment will be ready for operation this summer, and will produce about 300 tons of concentrates daily, yielding about 1,000,000 pounds of copper per month at a very low cost. Experimental work with the 80-ton sand-leaching plant was successful, and there is now under construction a 2,000-ton plant. Further experimentation has been authorized on slime tailings. Coal-dust firing of reverberatories is under trial, following an investigation of this practice at different places in this country and Canada. The reconstruction of the smelting plant at Great Falls is progressing nicely. It is the intention to abandon the concentration of ore at Great Falls, doing all this work at Anaconda and shipping concentrates to Great Falls for smelting.

**The American Zinc, Lead & Smelting Co.** reports that in 1913 the zinc industry was in an extremely unsatisfactory state, and as a result of unfavorable conditions the company sustained a loss from operations amounting to $91,656. This was augmented by other items, including one dividend of $85,600, to a total loss, charged against surplus, of $304,630. The physical condition of the company's smelters and other plants is good, and with a return to normal conditions in the zinc industry will be able to show substantial earnings. The new smelter at Hillsboro has made no profit, owing largely to starting under the unfavorable conditions mentioned. The Tennessee property is proving highly satisfactory, an important feature being that the tailings from the mines can be used for railroad ballast, road construction, concrete work and roofing material. The fine slime can be sold for limeing the soil of farms in Tennessee and surrounding states. This disposal of tailings may expand to such an extent as to amortize a large part of the original cost of property and equipment.

The eighth annual report of the **United States Smelting, Refining & Mining Co.** shows the following production of metals in 1913:

| | | Per cent of total value | Average price received |
|---|---|---|---|
| Copper .... | 20,239,973 lb. | 18.8 | $0.15433 per lb. |
| Lead ...... | 58,116,504 lb. | 15.3 | .04396 per lb. |
| Silver ..... | 13,089,708 oz. | 47.3 | .60503 per oz. |
| Gold ...... | 148,372 oz. | 18.6 | |

Net earnings for the year amounted to $3,585,586, and dividends totalled $2,755,466. The report of the exploration department shows that the company was tendered 614 properties during the year, of which 190 were rejected on office examination of reports and data submitted. A preliminary field examination was made of 100, and a complete examination and sampling of 24 was undertaken. Three groups of claims were bought: the Last Chance, adjoining company property at Bingham, Utah; La Reunion group connecting the Real del Monte and Pachuca properties in Mexico, and the Spread Eagle group in Shasta county, California.

## The Iron and Steel Market

For the first time since January there has been a definite and important improvement in the iron and steel market. Beginning approximately with the first of June pig iron buying increased and the volume of steel orders improved.

In pig iron the movement was largely seasonal in that the contracts of consumers began to run out and as prices were attractively low there was a disposition to cover for third quarter requirements.

In steel there had been only desultory buying for several months. While buyers probably accumulated some stocks as a result of the January buying movement, in April and May they followed a steadfast policy of reducing stocks to the utmost.

Orders for prompt shipment of steel products booked in June probably averaged between 25 and 40 per cent more than the corresponding bookings in May, which was easily the poorest month in this respect since December. It did not follow that production and shipments increased in like measure, because some of the shipments in May were the result of earlier commitments and some increase in buying was necessary merely in order that buyers should continue to receive as much material as formerly. There was, however, an excess, whereby mill shipments have probably averaged a somewhat larger tonnage in the past month than in May.

While buying for prompt shipment increased, a disposition appeared to buy for forward delivery. There had previously been scarcely any forward buying. The disposition to buy for forward delivery was partly seasonal, but it represented in larger part a recognition that prices for steel products were extremely low. In March, for instance, there was no disposition to buy for second quarter shipment as a whole, because prices had advanced not long before and were then showing a declining tendency.

With bars, plates and shapes available at 1.10c. black sheets at 1.80c. and galvanized sheets at 2.75c., all for prompt shipment, buyers began to negotiate for third quarter contracts at these figures. In practically all instances the mills quoted higher prices, by $1 or $2 a ton, and the third quarter business closed has been chiefly at advances of about a dollar a ton over what could be done for immediate shipment.

The present prices are extremely low relative to the cost of production. It will be recalled that a very low point was reached in November, 1911, the lowest average since early in 1899, when conditions were so different that reasonable comparisons cannot possibly be made. The average price of finished steel products to-day is not as much as a dollar a ton above the low level of two and a half years ago. At that time the mills made practically no money. Since then the general wage level has been advanced and with mills operating at a lower rate than then their cost of production is automatically increased.

The June improvement in buying is not in itself of much significance. Early in April it began to be said that steel market conditions had become so bad that there could be no change except an improvement. The June movement in itself has not been as pronounced as was that of last January, and yet that movement played out, leaving no lasting effect. The present movement is lesser in degree and if it is similar in kind it gives no particular promise. In some quarters it is maintained that this is the beginning of a long and important movement and that the market will not soon again see such stagnation as characterized April and May. The test of the theory will come quickly. July is normally a very dull month, and if the market resists its soporific influence it will prove that there are still better things to come month by month.

The United States Steel Corporation's unfilled orders decreased 376,757 tons in April and 278,908 tons in May, leaving the unfilled tonnage at the beginning of June 3 998,160 tons, of which tonnage it is to be presumed only a relatively small proportion was for shipment within the month. Conditions in June have been such that there is a prospect that the report to be made public July 10 will show an increase for the month in the unfilled tonnage.

Steel production and shipments during June have been at fully 60 per cent of the entire mill capacity, showing no important change from May. In July many mills will close for repairs and shipments are not at all likely to increase.

Car buying was slightly heavier in June than in May. In the first half of the year fully 60,000 freight cars were ordered and this is really a fairly good showing considering what drastic policies of retrenchment are in force with the railroads.

### Pig Iron

Early in June the leading cast iron pipe interest purchased 67,000 tons of Southern pig iron for second half delivery, while export orders for about 40,000 tons of Southern iron were closed at about the same time. The business developed a lower market price in Southern iron by 25 cents a ton, but at the same time greatly increased interest in the pig iron market in general. It is normal for Southern iron to lead the general pig iron market, in both upward and downward movements. Buying of pig iron has since been more general in all districts, though the movement is by no means as pronounced as was that of a year ago when conditions in pig iron were more or less similar to those of the present. Production of pig iron has been at the rate of about 24,000,000 tons a year in June, comparing with the maximum rate of this year of 28,000,000 tons, reached in March and April, and a record high rate of 34,000,000 tons, reached in February, 1913. The market is quotable as follows: No. 2 foundry, f.o.b. Birmingham, $10.25; delivered Philadelphia, $14.50 to $14.75; f.o.b. furnace, Buffalo, $12.75 to $13; f.o.b. furnace, Chicago, $13.50 to $14; at valley furnaces (90 cents higher delivered Pittsburgh) No. 2 foundry, $13; basic, $13; malleable, $13 to $13.25; gray forge, $12.50 to $12.75; Bessemer, $14.

### Steel

As a rule, consumers of billets and sheet bars did not absorb their full contract tonnages in the second quarter and with considerable tonnages being carried over July 1 they have been slow to negotiate fresh contracts. While little has occurred to develop actual market prices it is recognized that the market is quotable at about $19.50 for billets and $20.50 for sheet bars, f.o.b. makers' mill, Pittsburgh or Youngstown, these prices being 50 cents a ton below the nominal figures named a month ago.

Rods can be had at $25, mill, or $1 a ton below the quotation of a month ago.

### Finished Steel

Prices quoted below show a slight decline, on the whole, during the month. They are for prompt shipment, contracts covering a period of three months usually bringing about $1 a ton more. Quotations are f.o.b. Pittsburgh, unless otherwise noted:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.10c.

Steel bars, 1.10c., base.

Shapes, 1.10c.

Iron bars, 1.25c., Pittsburgh; 1.22½c., Philadelphia; 1.05c., Chicago.

Sheets, blue annealed, 10 gage, 1.30c.; black, 28 gage, 1.80c.; galvanized, 28 gage, 2.75c.; painted corrugated, 28 gage, 2.00c.; galvanized corrugated, 28 gage, 2.80c.

Steel pipe, ¾ to 3-in., 80 per cent off list.

Steel boiler tubes, 3½ to 4½ in., 72 per cent off list.

Standard railroad spikes, 1.40c., Pittsburgh; 1.50c., Chicago.

Structural rivets, 1.55c.

Boiler rivets, 1.65c.

Cold rolled shafting, 66 per cent off list.

Chain, ⅜-in. proof coil, 3.00c.

## The Non-Ferrous Metal Market

During the past month the non-ferrous metal market has been dull, with comparatively little business transacted. Lead has proved strongest, showing larger sales and a good future inquiry. Tin has been unsteady and at times panicky. Spelter is dull and without feature.

**Copper.**—Prices have tended toward weakness and sellers have offered inducements to the trade. At the low level of prices buyers are showing some interest, but are not yet buying heavily. Electrolytic copper is quoted at 13.7 cents, New York. Sales of Lake are reported at 14@14¼ cents.

**Lead.**—This is the most active of the metals and fair sales are reported. Some small sales have been made for export. The market is steady at 3.90 cents, New York, and 3.82½ cents, St. Louis.

**Tin.**—The domestic market has been marked by fluctuations in prices, and the London market has been sensitive.

The latest quotation for June tin is about 31½ cents, New York.

**Spelter.**—Somewhat lower prices have prevailed in this market. Buying is slack and consumers have exhibited little interest. New York spelter is quoted at 5@5.05 cents, and St. Louis 4.85@4.90.

**Other Metals.**—Business in aluminium is quiet and orders are scarce. No. 1 ingots are quoted at 17½@18 cents, New York. Antimony is not specially active and various brands are quoted at 5.75@7.35 cents. A fair business has been done in quicksilver, the New York quotation being $37.50@$38.50 per flask of 75 lb.

San Francisco quotes $37 per flask for domestic orders and $2 less for export.

## Troy Meeting of the American Institute of Chemical Engineers

The sixth semi-annual meeting of the American Institute of Chemical Engineers was held in Troy, N. Y., June 17 to June 20. The meeting was opened at the Pittsburgh Building of the Rensselaer Polytechnic Institute by an address of welcome by Hon. C. F. Burns, Mayor of Troy, followed by an address by President Ricketts of the Rensselaer Polytechnic Institute, in which he referred to the rapid growth of the chemical engineering profession and the development of chemical engineering courses at the Rensselaer Polytechnic Institute and other technical institutes and universities.

The reports of the various committees and officers of the Institute were then presented. The Secretary reported a steady gain in membership which at present is 214. The Treasurer's report showed a substantial balance in the treasury. The Committee on the Standard Chemical Engineering Catalogue reported progress in drafting specifications for the Catalogue.

The following papers were then read: Mr. W. F. Rittman presented a paper on the Applications of Physical Chemistry to Industrial Processes and showed how problems in the manufacture of sulphuric acid, illuminating gas and the fixation of atmospheric nitrogen could be solved by physico-chemical methods. This paper is published in full on page 475.

Prof. J. W. Bain and Mr. A. E. Wigle presented a paper on Filtration, in which they showed the efficiency of filtration and washing of solids under various conditions. It was shown that the amount of liquid remaining in a solid was independent of the size of the particles but varied with the pressure.

Prof. Chas. Boskerville described a very efficient scrubber for vacuum apparatus for laboratories.

Luncheon was then served to the members of the institute by the Rensselaer Polytechnic Institute.

The U. S. Arsenal at Watervliet, N. Y., was visited Wednesday afternoon under the guidance of Colonel Gibson. The shrinking on of the outer jacket of a 14-in. coast-defense gun was witnessed as well as the very interesting operations of riflng the guns and winding guns with rectangular steel wire.

The testing laboratories and buildings of the Rensselaer Polytechnic Institute as well as the gymnasium building and swimming pool were then inspected.

After an informal dinner at the Hotel Rensselaer President Whitaker delivered an address in which he urged the desirability of greater publicity of the experience gained in chemical plants, especially with reference to failures of installations, disastrous accidents and explosions. Great benefit would result to the chemical engineering profession and chemical industries without the losses which would be involved in the publication of the details of successful processes. The address is printed in full on page 437.

Dr. L. J. Matos read a paper on shoddy and carbonized waste showing the methods by which woolen fibre is recovered from rags containing cotton and made available for spinning and weaving. The great economy of this utilization of waste material was emphasized especially in view of the shortage of raw wool. The superiority of much of this recovered wool to many grades of raw wool was shown. The impossibility of distinguishing, in the finished fabric, between raw and recovered wool was also explained. The length of the fibre cannot be used as a test because various grades of the raw wool contain both long and short fibres.

Prof. Wm. P. Mason then showed a number of lantern slides of the Saratoga septic tanks and explained their operation and also discussed a remarkable explosion of one of these tanks, the cause of which has not been clearly demonstrated. Professor Mason suggested the possibility of the combustible gases produced by the bacterial action having been ignited by phosphine produced by the same action.

On Thursday the plant of the General Electric Company at Schenectady was visited. The entire process of manufacture of dynamos and steam turbines was inspected. Special interest was shown in the mercury-vapor engine in course of development, which shows an efficiency 50 per cent higher than the ordinary steam engine. The new Research Laboratories were also inspected, after which lunch was served by the General Electric Co.

The members then proceeded by a special private car of the Schenectady R. R. Co. to Saratoga, where they were shown the springs and the state reservations by the resident physicians who furnished their automobiles for the purpose. After inspection of the sewage disposal plant the return trip to Troy was made in the special car.

In the evening the members took dinner at the Troy Club, after which addresses were made by President M. C. Whitaker, Prof. Wm. P. Mason, Dr. Chas. Ferris of the State Reservation Commission, Prof. Edmond O'Neil of the University of California, Prof. James R. Withrow, Prof. A. M. Green of the Rensselaer Polytechnic Institute and Secretary Olsen. Prof. O'Neil extended an invitation to the Institute to meet in San Francisco in September, 1915.

At the meeting Friday morning at the Hotel Rensselaer, Professor Withrow reported that the Committee on Chemical Engineering Education is cooperating with the Carnegie Foundation in its investigation of the chemical engineering courses given in American colleges and universities and that the Carnegie Foundation has engaged Dr. C. R. Mann to inspect the institutions giving such courses.

The following papers were then read: Mr. John C. Hebden gave the results of a careful study of the chemistry of the bleaching of cotton fibre. He presented analyses giving the composition of the raw cotton as well as its composition after each of the processes of cleaning, bleaching and washing.

Dr. J. C. Olsen and Mr. Wm. H. Ulrich reported the results of experiments showing that ozone oxidizes many substances producing odors, and pointed out many serious errors in the article by Jordan and Carlson on Ozone.

Mr. Maximillian Toch, in a paper on the present patent situation, showed that the new rules for the taking of evidence in patent litigation are not being observed on account of the failure of the United States Government to provide a sufficient number of judges to hear patent cases. Dr. M. H. Iltner also read a paper on patent abuses.

On Friday afternoon the manufacture of collars and shirts was inspected at the factory of Geo. P. Ide & Co. The plant of the West Virginia Pulp and Paper Co. at Mechanicsville was then visited, where both the sulphite and the soda process as well as the electrolytic production of soda and bleach liquor were shown.

Friday evening Mr. L. M. Booth presented a paper, illustrated with lantern slides, on a combination water softener and storage tank. In this installation the calcium and magnesium salts are rapidly precipitated by chemical treatment and mechanical agitation while the clear, softened water is taken off at a suitable height above the sludge. Filtration is thus rendered unnecessary. By making the tank of a sufficient size storage is provided for.

Mr. Richard K. Meade presented a paper giving the developments of the rotary furnace and suggested a number of new applications for this type of furnace. Numerous lantern slides were shown.

The members were entertained at a smoker at the residence of Dr. Wm. P. Mason and were given the opportunity of meeting President Ricketts of the Rensselaer Polytechnic Institute.

On Saturday the plant of the Burden Iron Works was visited where the puddling process for wrought-iron was shown. The attendance at the whole meeting was excellent.

The winter meeting of the Institute will be held in Philadelphia early in December. Dr. John C. Olsen, Polytechnic Institute, Brooklyn, N. Y., is the secretary of the Institute.

## Ninth International Congress of Applied Chemistry

The Executive Committee of the Ninth International Congress of Applied Chemistry, to be held in St. Petersburg, Russia, in 1915, has just issued its first Preliminary Announcement.

The Congress will open on July 26-August 8, and close on August 1-14, the second dates in each case being the dates in the new-style calendar. That is, according to the calendar in use in the United States the Congress will be held[*] from August 8 to 14, 1915.

The Emperor of Russia will be the Patron of the Congress. D. P. Konovaloff, Assistant Minister of Trade and Commerce, will be the Honorary President. Professor P. I. Walden will be the President. Major-General Professor W. N. Ipatiew will be the Honorary Secretary.

All letters are to be addressed to the Honorary Secretary, Ninth International Congress of Applied Chemistry, Winter Palace Place 8, St. Petersburg, Russia (cable address Chimicongress, St. Petersburg).

The membership fee is ten roubles (equivalent to about five dollars), payable in postal money order or check on a St. Petersburgh bank, to the Treasurer of the Congress, V. T. Schaefer, whose address is also Winter Palace Place 8, St. Petersburg.

Applications for membership must contain the applicant's full name, exact address, profession and name of Section or Subsection in which he wishes to take part.

Membership fee must be paid not later than April 1, 1915, if delivery of the printed Transactions is to be guaranteed. The printing of papers will begin in April, 1915, and the size of the edition will depend upon the number of membership fees received on or before April 1-14, 1915.

Ladies accompanying members of the Congress may receive tickets upon the payment of seven roubles. These tickets entitle them to all rights of the Congress with the exception of the right of participating in debates and administrative affairs. Such tickets do not entitle the owner to receive the printed Transactions of the Congress.

"To insure free passage into Russia for all members as well as for ladies accompanying them it is necessary to show at the frontier, in addition to passports with visa, membership cards, signed by the President and Honorary Secretary of the Congress." (In the *Percolator* the same statement is expressed as follows: No obstacles will be placed in the way of the journey of Jewish chemists to the Congress provided that at the frontier, in addition to the vised passport (requisite for every passenger), cards of membership, signed by the President and Honorary Secretary of the IX International Congress shall have been presented.)

---

[*] In the *Percolator* of the Chemists Club of New York of June 18 it is stated that the Congress will be held from August 20 to 26, 1915. This statement is based on the authority of a letter of President Walden of Feb. 20, 1914. We are unable to explain this discrepancy of the dates, but assume that the correct dates are April 8 to 14, as stated in the official Preliminary Announcement, just issued.

The official languages of the Congress shall be Russian, French, English, German and Italian.

The list of the 22 sections and subsections is as follows: 1. Analytical Chemistry. 2. Inorganic Chemistry. 3. Metallurgy and Mining. 3b. Explosives. 3c. Ceramic and Glass. 4. Organic Chemistry. 4a. Colors. 5a. Sugars. 5b. India Rubber and other Plastics. 5c. Fuels and Asphalt. 5d. Fats, Fatty Oils, Soaps and Drying Oils. 6a. Starch, Cellulose and Paper. 6b. Fermentation. 7. Agricultural Chemistry. 8a. Hygiene. 8b. Pharmaceutical Chemistry and Pharmacology. 8c. Chemistry of Foods; Physiological Chemistry. 9. Photochemistry. 10a. Electrochemistry. 10b. Physical Chemistry. 11a. Legislation relating to Chemical Industry. 11b. Political Economy and Conservation of Natural Resources. (The only essential difference from the arrangement of the sections at the Congress in New York City, 1912, is that the former subsections 5e. and 8d. have been abolished and combined with other sections.)

## Paris Meeting of the British Iron and Steel Institute

The autumn meeting of the (British) Iron and Steel Institute will be held in Paris on Thursday, Friday and Saturday, Sept. 17, 18 and 19. On the conclusion of the meeting in Paris a visit will be made to Nancy and to the principal iron mines and metallurgical works of French Lorraine.

The meetings in Paris will be held in the House of the Comité des Forges, Rue de Madrid, Paris.

Mr. G. C. Lloyd, 28 Victoria Street, London, S. W., is the secretary of the Institute.

## A Mine at the Panama-Pacific Exposition in San Francisco, 1915

The U. S. Bureau of Mines has undertaken to construct, in cooperation with the mining industry and the manufacturers of mining machinery, a mine beneath the floor of the Palace of Mines and Metallurgy at the Panama-Pacific Exposition.

Typical metal and coal mining operations will be reproduced by full-size working places in which mining machinery will be installed and operated. The walls of the mine will be covered with either ore or coal typical of the mine illustrated. Among others, the Copper Queen Consolidated of Arizona, Bunker Hill Sullivan Company of Idaho, Homestake Mining Company of South Dakota, Goldfield Consolidated Mines company of Nevada, Jones and Laughlin Company of Michigan, Lehigh Coal & Navigation Company of the anthracite field of Pennsylvania, Pocahontas Fuel Company of West Virginia, Consolidation Coal Company of Kentucky, and Pacific Coast Coal Company of Washington, have each agreed to reproduce one of their working places or stopes and to contribute the sum necessary to the installation and operation. Tentative promises of similar action have been received from the Rock Island Coal Company, Peabody Coal Company, and Pittsburgh Coal Company.

Various mining machinery and appliances have been promised, including a mine cage and cars by the Joshua Hendy Company; a cage, hoist and motor by the Denver Engineering Works; locomotives by the Westinghouse Electric & Manufacturing Company; pumps by Byron Jackson; air compressor, drills, drill sharpener and winze hoist by the Compressed Air Machinery Company; drills and coal cutters by the Ingersoll Rand Company and the Sullivan Machinery Company; lamps by the Justrite Manufacturing Company and the Koehler Manufacturing Company; enamel signs by Stonehouse Enamel Sign Company.

The entrance to the mine will be through the Bureau of Mines space, and visitors will be attracted to it by being given portable mine lamps, and by being lowered in a very slowly moving cage while a panoramic effect of the strata lining a mine shaft will pass by them so rapidly as to produce the illusion of descending to a considerable depth. In case of crowds, these may enter by a slope. Exit will be by a slope into the radium booths of the Bureau of Mines where radium emanations will be shown.

There will be a motion-picture room which visitors will pass in going from mine to mine. In it will be shown such great open workings as are not illustrated by the underground mines, such as those of the Utah Copper Company and those of the Nevada Consolidated Company at Ely, the iron diggings at Hibbing, Minn., hydraulic gold mining, and the quarrying of building stone.

Twice each day there will be an imaginary explosion or fire in some portion of the mine announced by telephone to the superintendent's office in the Bureau of Mines space on the surface, and rescue men wearing breathing apparatus will enter the mine and bring out supposed victims who will be given first aid treatment in the surface emergency hospital.

In the Bureau of Mines space on the floor of the main building, there will be, in addition to the radium booths, exhibits of carnotite, pitchblende and other radium ores, their alloys and concentrates, an emergency mine hospital and smoke room for rescue training, exhibits of fuel efficiency, smoke abatement, explosives, mine welfare work, etc.

The prime purpose of the mines will be that of educating the investing public, stockholders, members of legislatures and the uninformed antagonists of the industry relative to the importance of the mining industry, its extent, variety and the cost of operation.

---

Electric Hoists of one-ton or two-ton capacity are the subject of Bulletin 301A of the Pawling & Harnischfeger Co., Milwaukee, Wis. The system here described should be particularly attractive for such industrial plants in which hand labor is still employed for lifting loads and carrying them over short distances. In such plants an electric hoist with 200 or 300 feet of runway will in most cases pay for itself inside of a few months as it will replace from three to ten men, depending on conditions, and can be easily and quickly installed. The design in question is an overhead monorail hoist, traveling on the lower flanges of an I-beam. The illustrations in the bulletin show the application of this hoist for lifting heavy paper rolls in a printing shop, for handling pipes, rods and plates in steel works, for carrying boxes in a warehouse, etc. When the hoist is equipped with electromagnets for handling iron bars, plates, etc., the operator handles the load alone without other help. Another illustration shows the very complete monorail system with turntables, crossovers, switches, etc., installed at the International Harvester Co.'s plant at Milwaukee, Wis.

Calendar—"Again we say what is so rare as a day in June for a new calendar?" The Wagner Electric Company of St. Louis, Mo., has issued a very attractive calendar, covering the period from June, 1914, to May, 1915. The picture on the calendar is that of a little boy in quiet but evident admiration of a little motor.

# Some Professional Obligations*

BY M. C. WHITAKER

Chemical engineering as an organized profession is comparatively new, although many men have been engaged in this class of work since the beginning of large-scale manufacture. Since the organization of this Institute, various definitions have been given to outline the scope of our professional activities, many schemes have been suggested to improve the training of our apprentices, some advances have been made towards standardization in our engineering practice, a code defining the ethical standards of our profession has been formulated and adopted, and we have shown our aims, with some results, in constructive patent reform.

Work of such a character is of the greatest importance, and is far in advance of that heretofore undertaken by any other organization in our field. It can never be regarded as completed, and the best thought and effort of well constituted committees will continue to be given to advancement along these lines, with great resultant benefit to the profession.

There comes a time, however, in the life history of every organization or enterprise when the greatest advancement and improvement may be made by a process of introspection. It would seem to the speaker that chemical engineers might now, with great profit to themselves and benefit to the profession, submit to a process of self-analysis. Obviously it would be out of time and place to attempt now a profound or philosophical analysis of our internal personal relations and aims, but it is hoped that by reference to a few of the more fundamental points we may thereby catalyze some productive reactions.

Chemical engineering must, sooner or later, come to be recognized as the leader among the engineering professions. Its interests are larger and more varied, and its scope is greater and more intimately related to social and industrial progress than that of any one or all of the other branches of applied science. Manufacturing output in the United States, which in money value is already almost equal to the largest single productive interest, will be dependent in some, if not in all, of its steps upon the chemical engineer. The burden of the development of the industrial processes and the operation of the plants will fall upon him, and naturally the rewards of success and the odium of the failures will be his. The realization of the opportunities of such a profession, so full of brilliant promise and great possibilities, will depend in a large measure upon the breadth of view adopted in the acceptance of our responsibilities.

A voluble assertion of our importance will not give us the power to master our calling. Professional prestige, in the engineering field at least, is built upon achievement. Achievement worthy of the dignity of a profession cannot be built upon independent work, the spectacular results of a few individuals or the hit-and-miss strokes of fortune. It must be based upon a consistent development of and by a body of able progressive men, and be based upon years of unselfish constructive co-operation, in which each member contributes his share, and in turn, draws freely from the common store.

The legal, the medical and the clerical professions have devised for themselves some form of legal protection. The engineering professions, on the other hand, are subject to no form of external control, and may become self-developing or self-effacing according to the wisdom of the policies adopted in their direction and development, and the positiveness and value of their achievements. Merit, after all, is the only measure of success in engineering, and all failures, and even doubtful results, are promptly charged off against the profession.

The civil engineer may design and build a bridge. During construction his work is open and in full view of the public and his colleagues. There is not a single feature of his purpose, his design or his materials of construction which is not common knowledge to anyone who takes the trouble to look at his work, or read any of the numerous articles published during its progress. Even the lay public may be interested and pay their tribute to the man behind the work. The finished bridge stands in public as a monument to the power and ability of the builder and the profession he represents.

The mechanical engineer may design and build a wonderful machine. There is no secret about any of the features. His colleagues, the public, or anyone may study and criticize his work, accept and profit by his suggestions and ingenious features, or may avoid his mistakes. The mechanical engineer has profited by the successes and failures of his predecessors in the art, and his successors, in their turn, will build better as a result of his work.

So it is with the mining and the electrical engineer. Each works with a full knowledge of what has gone before; each contributes his share to the advancement of his art, and the standing of the professions is enhanced because of his contributions.

The chemical engineer, on the other hand, works in unappreciated silence behind factory walls. He is not building a monument which invites public approval, though he may be making a product of equal value and more wonderful if it were understood. The details of his work are carefully guarded, and he is even denied the stimulus of public interest in his achievements. His designs, materials and methods often lack the helpful suggestions of his fellow engineers. He may repeat at great expense the mistakes previously made by his neighbor, or may fail to avail himself of well worked out methods which are unknown to him on account of lack of proper exchange of professional knowledge.

If he is secretive it comes as a result of environment and conditions. This secretiveness often becomes a habit and is assumed to be a necessity. At times this habit is extended either unconsciously or accidentally to ludicrous limits.

For example, note how difficult it is to find the professional or business connections of a chemist or chemical engineer. Surely there is nothing about this which should be concealed. On the contrary, good would result both to him and his employer by having his connections and field of activity well known. The directories of all other engineering societies contain valuable information about the professional activities of their membership, while our directories in many cases carefully disguise even the business addresses of our members.

The chemical engineer's efficiency in the production of successful results is reduced to a minimum, because of a lack of liberal professional co-operation, while civil, mechanical, electrical and other engineers are steadily improving their professional efficiency by a systematic exchange of principles and practices, and a selective action to carry forward the good methods and reject the bad ones. We of the chemical engineering profession are harboring conditions which retard or frequently even prevent professional progress.

When the work of the chemical engineer is not open to public view, his productive efforts not understood, and therefore not appreciated, his achievements cautiously guarded, his business connections withheld from the directories of his societies and absolutely no record of his professional activities is made available, is it any wonder the lay public usually think of him as a druggist?

---

*Presidential address delivered before the American Institute of Chemical Engineers on June 17, 1914.

If one traces the life history of the development of the chemical engineer, it will be found that we have some bad traditions to overcome. Our alchemist forefathers cultivated secretiveness, mystery, and even deception. These dark-art traditions are openly professed to-day in some of our factories, while in others they remain in latent evidence.

With these adverse conditions and traditions in existence it would seem that the chemical engineers are confronted with an important problem which intimately concerns the progress and development of the profession. Inefficiency and loss of prestige are bound to result from unsupported individual effort. Co-operation is essential to substantial engineering development. This co-operation comes about naturally in other engineering professions, and it will have to come, if not naturally then by force of necessity, in ours.

Every failure in design, every fatal accident, every industrial disease, every fire or explosion in a chemical works, every commercial insuccess is an indictment against the chemical engineering profession. Cause and effect in bridge failures, dam failures, boiler explosions, railroad and steamship wrecks, are freely discussed in conventions and journals for the benefit of the interested profession. These open and frank discussions disarm public criticism on the one hand, and on the other place before all members of the profession most impressive and profitable lessons in what not to do.

The chemical engineer in such cases, apparently guided by his ancient traditions, or his environment controlled habits, as no other motive seems discernible, often secretes the facts not only from the public hut also from his professional associates. Such secretiveness always arouses public suspicion. The interests of humanity may be sacrificed, and the profession, without the knowledge of what has happened, may go blundering into the same disaster again and again. These costly disasters are not even recorded as experience outside of the factory walls in which they occur.

Have the chemical engineers discussed or even heard of the causes leading to the failure of the coke plant at Bethlehem; the cause and effect of the explosion in the artificial leather factory at Detroit; the lessons to be drawn from the recent fire in the Mallinckrodt works in St. Louis; the cause and effect of the failure of a large gas holder at Philadelphia; the cause or remedy of the large number of industrial diseases in some of our plants; the complete failure of this or that piece of equipment or method of installation?

Do the affected or afflicted chemical engineers seek the assistance of their associates and professional colleagues in determining the cause, and suggesting the remedy for such disasters? If the cause and the remedy are determined, are the facts made public?

Think of the benefit which would come to our profession and to humanity and industry in general from frank authoritative discussion of these and many other problems which come within the experience of every chemical engineer. The discussion of the defective design, or material, or installation of chemical engineering appliances is a thing which would be of inestimable benefit, not only to other engineers, but also ultimately to the producers of the appliances. Negative results can be of no possible value to those industries which have developed them, but if they were published or discussed they would become of the greatest importance to future engineering progress. Why should they be jealously guarded and secreted and the progress of this profession thereby blocked?

The question as to what knowledge the manufacturer should disclose for public use and what should be kept within the factory walls is one which may be settled by the rule of reason, but never settled by yielding to the inclinations of our natural environment and our ancestral traditions. When it becomes clear that these conditions are blockading engineering progress and our own professional development, it will not be simply a duty, but an obligation, for every chemical engineer to apply this rule of reason.

Property value might safely be accepted as the basis for determining what should and what should not be disclosed. Manufacturers and chemical engineers would not be expected to give out unprotected information of direct property value any more than civil engineers would be expected to publish their working drawings before the contracts were awarded, or the mechanical engineer be expected to give away the appliances in which he had invested his time and his money. Such a policy would result in commercial anarchy and tend to destroy industrial stability and with it the dependent professions.

Fortunately it is very often the knowledge having the least property value which, when collected and classified, possesses the greatest professional value. Negative results can usually be disclosed without loss and they form the most substantial basis for engineering development.

On the other hand, the publication of the failure of a design, a material or a process would invite constructive thought from others which might turn a failure into a success, or suggest to our young investigators researches which would definitely establish or disprove the scientific validity of the principles involved.

The interests of humanity demand that industrial diseases, industrial accidents and improvements in working conditions be openly and frankly discussed in order that the combined effort of all minds be brought to bear on the needed solutions. Proper publicity in all bad or doubtful cases would do much to soften the hearts of the financial control, and at the same time independently enlist the services of the physiological chemists, the medical researchers, the mill designers and many minds in our own profession which is most seriously indicated.

We have all heard the statement by members of this profession that there are no adequate textbooks or handbooks in chemical engineering of the same standard of excellence as those existing in mechanical engineering, for example. Such books, in any engineering field, are the results of compilations and classifications of approved matter from current technical journals and society proceedings, and it is inevitable that they will be large or small, dense or rare, profound or superficial, in direct proportion to the current available material.

If we secrete our information, or fail to publish our researches, hoard our knowledge and avoid the full and frank discussion of our industrial problems, we are bound to reap the negative rewards. Our books will not represent the sum of a profession's knowledge, but instead the comparatively small, laboriously attained work of one or a very few individuals.

This institute, representing as it does the leading organization devoted exclusively to developing the technical interests of the chemical engineers, and enhancing the prestige and value of that profession, should be the first to consider all obstacles to the accomplishment of its purpose. Our profession is built upon the applications of a science of the most infinite and varied detail. The mastery of modern chemistry requires a highly developed mind and one which should be fully qualified to attack and solve with ease the problems of policy in the development of the profession.

Our organization is new and the problems are large and numerous. Most careful consideration must be given to the direction of our energies into those channels in which we shall find the most productive returns. We have no time to waste on philosophical quibbling or fussy arguments. If self-analysis shows that the indictment of narrowness is valid and that the best interests of our profession will be served, as I think they will, by a more active interest in public questions, such as the so-called conservation movement, public service control, corporate regulation, financing of industrial enterprises, etc., then we should study and discuss these problems in our meetings and proceedings.

If chemical engineering education is twenty or thirty years behind the methods and efficiency of mechanical and electrical engineering training, as I think it is, and its improvement is being blocked by the dogmatic teaching that chemical manufacture is nothing more than enlarged laboratory practice, it then becomes evident that even more strenuous efforts will be required from this institute and its hard working committees to produce the desired results.

If, as I firmly believe, our professional progress is being seriously blocked by an unjustified and unjustifiable veil of secrecy or mystery drawn around our experiences, our needs, our achievements and our professional activities, the removal of this obstacle to our advancement becomes an obligation upon each constituent member of the chemical engineering profession, and particularly upon the Institute of Chemical Engineers.

Chemical Engineering Laboratories,
Columbia University, New York.

## Physical Versus Chemical Actions in Furnaces

BY CARL HERING

In many furnace processes, aside from simple melting, there are often both chemical and physical changes which either consume or set free energy, hence must be considered in processes in which the cost of the electric energy is of importance.

In books the energy involved in a chemical change or reaction, and generally though erroneously called "heat" of combination, is given in a lump sum regardless of how much of it is for the purely chemical part of the total and how much for the physical parts which may be involved in the change. By a chemical change is here meant a rearrangement of the atoms which results in a different chemical compound or product; by a physical one is meant a change of state of any parts of the material, say from solid to liquid or gas, or to a solution in a solvent, or a change of temperature, etc., hence it includes all changes other than the chemical ones.

For instance, when $Fe_2O$ is combined with C in a pig-iron blast furnace,, the chemical changes are the reduction of the iron oxide and the oxidation of the carbon; while the physical changes are the liquefaction of the solid iron and the vaporization of the solid O and the solid C into a gas, hence involving an enormous expansion against atmospheric pressure (about 7000 to 8000 fold) and the latent heats of both fusion and vaporization of C and O.

In books the enegies involved in these various changes are jumbled together into one amount. The object of the present note is to call attention to the desirability of separating them into their component parts, at least for electric furnace processes in which the energy consumption is important; by thus separating the parts of the whole into the chemical and the physical energies, it may sometimes be found to be cheaper to do the physical part by other means than by electric heat or it might be possible to prevent an energy consuming physical change from taking place, or perhaps even bring about an energy producing one; the purely chemical changes might perhaps also be facilitated in such ways.

When we know how much of the energy involved in a furnace process is physical and how much is purely chemical, it becomes possible to estimate whether that process might perhaps be cheapened by saving some of the energy involved in the physical part or by producing it more cheaply. The chemical changes, being the ones usually wanted, cannot of course be avoided, but even the energy involved in these purely chemical reactions might be modified by different physical conditions; for instance, near the temperature of the dissociation point of a chemical product the energy involved in making or breaking chemical bonds is much less, and this dissociation point might perhaps be raised or lowered as desired, by purely physical means other than heat, as for instance by pressure.

Some electric furnaces can be operated commercially at a positive or a negative pressure, and if this is an advantage, it might be possible to produce such pressures cheaply, thereby saving some of the electric heat.

If, for instance, a final product ordinarily leaves the furnace as a gas, but has entered it as a solid, as for instance in the production of zinc, arsenic, phosphorus, sulphur, etc., both the latent heats of fusion and vaporization must be supplied as electric heat, as must also the energy involved in the enormous expansion from a solid to a gas, and perhaps also the heating of this gas. But if by means of a positive pressure such a product could be kept liquefied in the furnace, and removed in that form, the energy required for these physical changes would not have to be supplied electrically to the furnace.

A negative pressure, on the other hand, might in other cases so reduce the vaporization temperature of a gas which is to be eliminated that less furnace heat would be required to accomplish its separation. Or in general, when a gas like CO or $CO_2$ is generated from solids and must be removed, it would consume less furnace heat to have it expand into a vacuum than against atmospheric pressure.

Numerous other cases might be cited to show the energy effect of the purely physical part of a process. Water might electrolyze easier in vacuum than if the gases must expand many hundreds of times against a pressure of 15 lb. per square inch, which consumes energy. Some of the impurities in molten steel might be more cheaply removed by a negative pressure (suction) than by chemical reactions, or than by calories alone, as in producing greater fluidity. If the oxygen in iron oxide is removed as a solid, by a solid, and the product is also a solid (or liquid), the energy for its expansion into a gas (physical) is saved; that is, there is no lowering of temperature due to this expansion; this is one of the causes of the high temperatures in the thermit reaction which is of this kind. If a gas, like hydrogen, combined with solid oxygen (in an oxide) the product being liquid water, the energy of the great contraction of the gaseous hydrogen to a liquid must be set free, hence is a gain and might perhaps be made to be available.

It is therefore thought by the writer that a clearer distinction between the physical and the chemical parts of a desired process may lead to a better understanding of what actually takes place; that is, it may give us a better mental picture, and this in turn might aid in improving or cheapening a process. Hence the writer claims that the energies of the chemical changes of compounds, or "heats" of combination as they are loosely called in books, should in future be stated in their component parts, with a clear distinction between the chemical and the physical, the latter being again subdivided into its constituent parts; the diminution of the chemical energy with a rise of temperature should also be stated. With this detailed data it would then become possible to estimate whether it might cost less to do the physical part in some other way than by expensive electric heat, or at least to facilitate it.

When the total "heats" of combination are thus resolved into their components, the speculative thought suggests itself that perhaps some of the apparently endothermic (energy absorbing) processes which take place spontaneously are in fact exothermic as far as the purely chemical part of the process is concerned, their endothermic character being perhaps due to the physical parts of the process.

When steam is heated to increasingly high temperatures, a point will be reached at which the chemical affinity of the hydrogen and oxygen becomes zero; this is known as the dissociation point; the molecules of these elements mixed together then have little more concern for each other than black and white marbles have when mixed in a bag. Their energy of chemical combination must therefore have been supplied during this heating process, yet all the heat that was added ostensibly merely increased the temperature, hence is, according to the books, classed under specific heat. This high temperature dissociation applies not only to steam but to most other chemical combinations.

It would be hard to believe that in such a case the energy of combination which was evidently supplied while the temperature was being raised, was taken up suddenly at any one temperature, like the latent heats of fusion and volatilization are, unless there is experimental evidence to this effect. It is more than likely that the real facts are, that as the temperature of a compound is gradually raised the chemical bond is weakened more and more until it becomes zero at the dissociation point; hence at that point all the energy of combination has been supplied to the material.

If that is the case, then what we call specific heat is not entirely such for compounds, but consists of two parts, a real specific heat and a part which goes to reducing the energy of the chemical bond, a physical and a chemical part; the chemical affinity grows weaker as the physical activity increases.

The rates at which these affinities thus decrease with a rise of temperature is apparently different for different chemical combinations, hence the curves representing them may and apparently do intersect in many cases.

If this is correct, then it does not seem irrational to suppose that in raising the temperature of the iron oxide, a portion of the energy of combination of the iron and its oxygen has really been supplied under the guise of specific heat (physical), and the bond has been weakened to such an extent that at the temperature of the reaction the affinity of the carbon for the oxygen exceeds it, and in that case the chemical reaction itself would continue spontaneously, as we know it does.

As explained above, there are moreover some purely physical changes in this reaction which must also be considered in the equations representing the energy transfers, or else they will mask the real actions. The carbon and the oxygen are changed from a solid to an expanded gas. The energy for these physical changes must be supplied from some source. If not added to the system the materials may be robbed of it, which means a lowering of the temperature; hence to keep up the temperature necessary for this chemical reaction heat must be supplied as fast as the oxygen and carbon are volatilized and the iron melted.

This necessary supply of heat has probably by some been erroneously supposed to be part of the energy of the purely chemical part of the reaction. It will readily be seen, however, that this part is purely physical and not chemical at all, though in using terms loosely the chemical and physical parts may have again been jumbled together in some books, just as the purely physical specific heats seem to have included parts of the chemical energy, as mentioned above. Carelessness in not distinguishing between the physical and the chemical parts of a process may lead to much confusion and erroneous deductions and conclusions.

*Philadelphia*, June, 1914.

---

**Sulphuric acid** produced at zinc and copper smelters is a factor of increasing importance in the acid industry of this country. According to figures compiled by the U. S. Geological Survey, the 1913 production from this source amounted to 790,296 short tons of 50 deg. acid, valued at $4,346,272. Copper smelters produced slightly more than zinc smelters.

**Statistics on the world's zinc industry** and trade have been compiled by the Department of Commerce from information furnished by the various U. S. consuls. The following tabulation gives the output of spelter for 1913:

| Countries | 1913 Short tons. |
|---|---|
| Australia | 4,105 |
| Australia and Italy | 23,856 |
| Belgium | 217,941 |
| France and Spain | 78,293 |
| Germany | 311,914 |
| Great Britain | 65,201 |
| Netherlands | 26,813 |
| Norway | 19,040 |
| Poland | 9,520 |
| United States | 346,676 |
| Total | 1,103,359 |

**Gas Producers.**—The Pittsburgh Plate Glass Company have just placed an order with the Chapman Engineering Company, Mt. Vernon, O., for five 10-foot inside diameter Chapman rotary gas producers. These are to be installed in their No. 11 Works, Mt. Vernon, Ohio, and supply gas for their two furnaces previously using natural gas. This is the second important installation of Chapman producers made by the Pittsburgh Plate Glass Company. The American Bottle Company are installing in their Newark, Ohio, plant one 10-foot Chapman producer to replace natural gas. This also is a second Chapman producer installation for this company. The American Clay Company, Terre Haute, Ind., have recently placed in operation one 10-foot producer, which replaces three hand-poked machines. The gas is used for burning hollow building tile in continuous kilns. The Chapman producer has reduced the coal consumption, decreased the time necessary to burn, and increased the percentage of good ware.

**Reserves of zinc concentrates** in the Joplin district, according to the authority of Mr. L. L. Wittich, are not acting as a bear on prices. They amount to 12,000 or 14,000 tons, the largest accumulation being 4000 tons at the Mont B mine. These concentrates cannot be bought at prevailing prices.

**The value of Utah's mine output** of gold, silver, copper, lead and zinc in 1913 was $44,858,210, according to the U. S. Geological Survey. This is an increase of nearly $2,000,000 over 1912. The silver production showed a slight decrease. There was a large increase in copper, the Bingham district producing 145,000,000 pounds. The total quantity of all ore sold or treated in the state during the year was 10,202,566 tons. The average recoverable value was $4.39 per ton. Gold production was valued at $3,565,229; silver amounted to 13,084,835 ounces; copper, 161,445,962 pounds; lead, 166,126,790 pounds, and zinc, 18,857,827 pounds.

# Electrolytic Refining of the Precious Metals

## The Plant of the Geneva Gold Refinery

BY H. LACROIX*

The electrolytic apparatus used by the Geneva Gold Refinery (Usine Genevoise de Degrossissage d'Or) for refining the precious metals has been described in detail in a previous article (see March, 1909, page 109-111 of this journal). The principle on which it works is well known and we will only give a description of the installation as it has been in operation during the last five years, together with the results which can be achieved.

At the Geneva refinery there are three different processes of electrolytic refining in use, namely, those of Dietzel, Moebius, and Wohlwill. The use of each depends on whether the alloy is rich in copper, in silver or in gold. These three different processes have led to the construction of three different types of apparatus, the design of which is based on the same principle but which vary in their dimensions in the materials of which they are made and in their shapes.

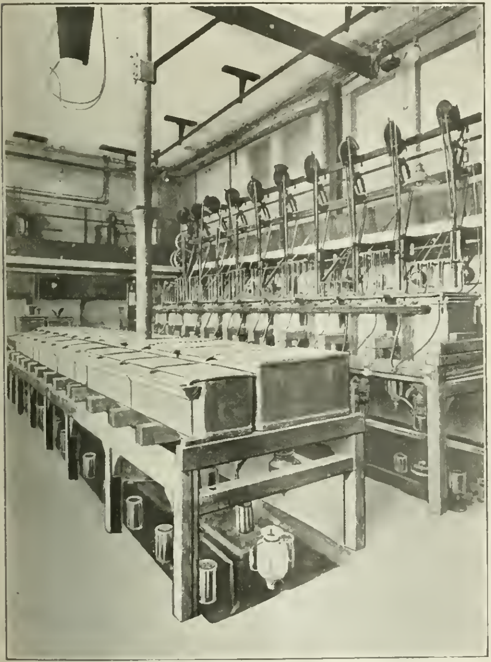

FIG. 1—INSTALLATION AT GENEVA REFINERY

Before describing these installations it will be of interest to say that few refineries labor under such unfavorable conditions as the Geneva refinery as regards the quality and the tenor of the alloys to be refined. With the exception of the refining of gold ingots from the mines, all the alloys refined in the gold refinery are derived from commercial bars, which are the residues of all kinds of work shops, poor in precious metal and containing large amounts of base metals, lead, copper, zinc, tin, nickel, aluminium, etc. In the Dietzel refinery the average content of gold plus silver scarcely exceeds 5 to 600 per thousand, and in the Moebius plant the average content of gold plus silver reaches 900 to 910 per thousand at the most. In spite of this all these materials are treated electrolytically without any preliminary chemical solution.

### Refining Silver-Copper Alloys

This installation (Fig. 1) consists of ten stoneware electrolytic tanks (Fig. 2) with four diaphragms each. The contents of the alloys treated here vary from 0 to 250 per thousand for gold and from 100 to 700 per thousand for silver.

The Dietzel process in use is well known. The desilverized solution coming from the desilverizing tanks is passed into an upper reservoir, where it is acidified, and is then distributed into the ten electrolytic tanks. The liquor is circulated in these tanks, passing from the cathodes, which are of copper, to the anodes (Fig. 3); these latter are suspended inside of diaphragms in which the silver collects. The liquor overflowing from the ten tanks is led through a common drain into a filter press and from there into a collecting tank. From there, by suitable tubing, it is distributed in the desilverizing tanks which are supplied with copper plates. These tanks are arranged in pairs one above the other; each pair is fed separately. After desilverizing, the liquor is collected in a common tank below, from whence an electric centrifugal pump raises it into the upper tank.

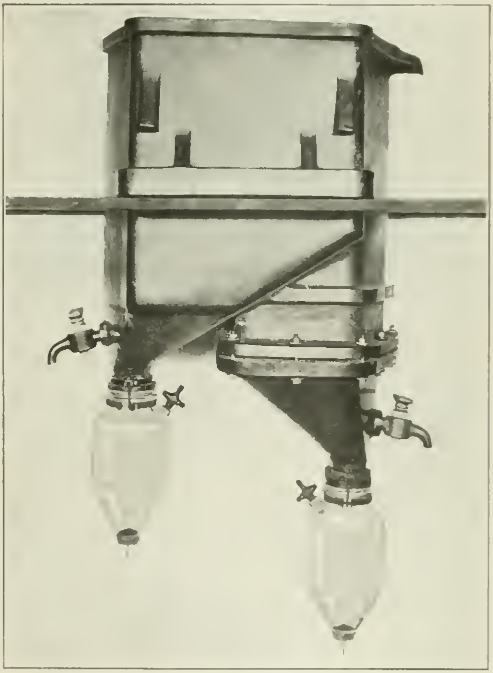

FIG. 2—ELECTROLYTIC TANKS

As electrolysis proceeds, the gold and insoluble anode residues precipitate and collect in the flask at the right-hand side, while part of the copper deposit which on account of the great density of the current does not adhere to the cathodes drops and collects in the flask at the left. These two precipitates are withdrawn by means of the arrangement described in the above-mentioned article; the arrangement consists of special flasks with globe valves which allow the removal of a stopper in the lower part. This operation is performed once a day with the flask containing the anodic residues; it requires only a few minutes to do this and no interruption of the circulation in the bath or the passage of the electric current is required.

---

*Translated by Alex F. Fuerst

The anodic gold can thus be withdrawn as fast as it falls and it is not necessary to wait for the complete consumption of the anode.

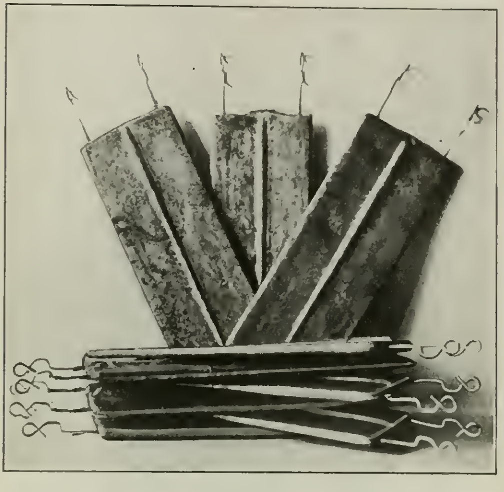

FIG. 3—ANODES

The silver which falls in the desilvering tanks, having a conical bottom, is withdrawn in the same fashion, twice in twenty-four hours. The silver is washed in a revolving drum and the wash water returns automatically to the tanks that fill the flasks after withdrawal. The current density employed is about two amperes per square decimeter.

### Refining the Silver

The type of apparatus used for this process differs from the previously described apparatus only in having the left glass flask (of the cathode side) replaced by a stoneware recipient of large capacity. The same is large enough to hold a twelve-hour production of silver and is connected with the tank by a large joint. The anodes are suspended inside of diaphragms and the withdrawal of the anodic residues is accomplished as described above.

The cathodes are of silver or aluminium, outside of diaphragms. The silver deposit is detached by scrapers which automatically scrape from above downwards; the silver falls into the stoneware recipient below, from where it is removed twice a day.

The principle on which this removal is accomplished is the same as above, though modified on account of the withdrawal of a large quantity in one operation. The flask with globe valve is replaced by a funnel provided with a globe valve. The funnel possesses an arrangement by means of which the stopper of the stoneware recipient may be drawn and its contents emptied through the funnel into a stoneware jar below, which is mounted on wheels. By means of this apparatus large quantities of material are withdrawn in a short time and its adoption in other branches of chemical industry should prove advantageous.

As in the previous plant, the bath also circulates from the cathodes to the anodes and is raised outside of the electrolytic tanks automatically from a lower collecting tank to a higher distributing tank.

### Refining the Gold

The electrolytic tank of the Geneva refinery has given excellent results in the two processes described above. But in its application to the Wohlwill process of refining gold it has been most successful, rendering this process efficient, rapid, producing a gold of great fineness and reducing manual labor.

The apparatus in use are in principle the same as described above for silver and copper; they are only smaller, have only two diaphragms, and are made of porcelain and the lower flasks are of glass. The anodes are suspended in pairs in each diaphragm from the busbars by means of silver hooks. The cathodes are clamped on top in groups of three on three busbars outside the diaphragms.

The chloride of gold bath (*loc. cit.*) circulates from the cathodes to the anodes, rising on the former and descending on the latter, after having passed through openings left in the upper part of the diaphragms.

The circulation takes place in the same direction as would naturally result from the change in concentration at cathodes and anodes of a bath that is left undisturbed. For high current densities such a natural circulation is much too slow, because a rapid impoverishment of the bath near the cathodes would take place and a bad deposit would result. In practice an internal circulation is established by means of a screw propeller.

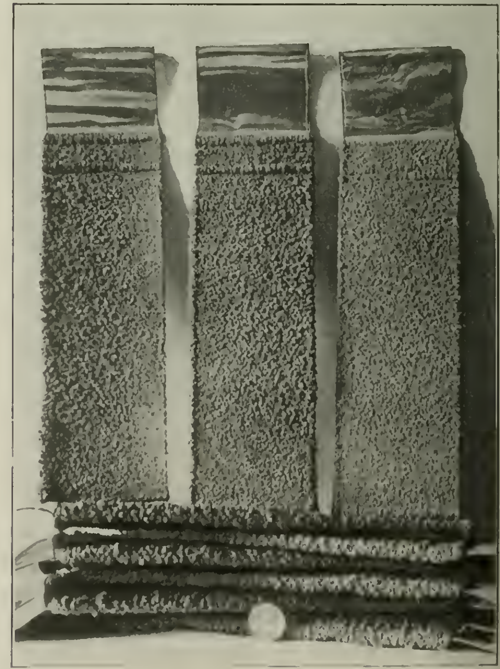

FIG. 4—CATHODES

This manner of circulating the bath in tanks without diaphragms has the drawback of stirring up the precipitate of chloride of silver so that small particles of it are carried mechanically to the cathode gold and lower its fineness. In some refineries such cathodes are once more refined by being used as anodes in other tanks.

By the use of diaphragms, however, in which the level of the bath is a few millimeters lower than on the outside, the chance of carrying chloride of silver towards the cathodes is absolutely excluded, no matter how rapid the circulation may be. The rapidity of circulation can, therefore, be greatly increased, especially with impure baths.

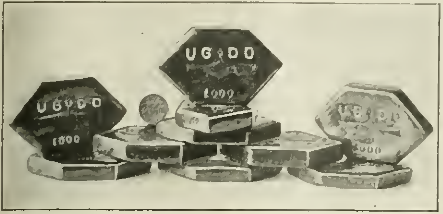

FIG. 5—MELTED CATHODE GOLD

As seen in Fig. 4 the deposit on the cathodes is absolutely uniform all over. In descending along the anodes the circulating bath becomes richer in gold, the particles of chloride of silver are detached and are carried along to the lower parts of the apparatus and collect in the lower flask by gravity. In the apparatus of the Geneva refinery the rate of circulation is about 5 to 10 liters per minute per square meter of cathode for an average bath. This represents a complete renewal of the cathodic solution within five to ten minutes.

The melted cathode gold (Fig. 5) always assays 1000 fine.

The gold bath on leaving the electrolytic tank runs into a lower tank from where it is automatically pumped by electric power into a higher distributing tank. From this latter it re-enters the apparatus after having passed a special steam-heating device where it acquires the necessary temperature. During this circulation outside the electrolytic tank the necessary additions of chloride of gold and of acid are made and a tank holding the wash waters, automatically keeps up the normal volume of solution and compensates for the loss by evaporation. The chloride of silver is removed once a day from the lower flask in the manner described above.

The current density can be pushed to 12 to 14 amp per square decimeter of anode, depending on the copper contents of the solution. The normal density is 9 amp per square decimeter at the cathodes and 11 amp per square decimeter at the anodes. This permits the refining of anodes of 8½ mm thickness in about thirty hours. The fineness in gold of the anodes is about 850 to 950.

For lower fineness a special arrangement is required for the removal of the chloride of silver: either pulsation current may be used, Wohlwill's patent,[1] or scraping of the anodes. The automatic scraper of the Geneva refinery possesses horizontal scrapers moving vertically in front of the anodes and pressing against them on descending, but receding on the rise. The anodes are thus scraped no matter what their thickness or their condition may be.

The diaphragms are sealed inside the electrolytic tanks with the exception of the openings in their upper parts, which establish communication between the anode and cathode baths. Good diaphragms resist well the action of the bath, in spite of its strong acidity and its temperature. Those actually in use have been working now for four years without any repairing.

Before concluding we wish to compare the cost, for example, with those given for the electrolytic operation at the San Francisco Mint, as described[2] in detail in the *Engineering and Mining Journal* of Nov. 4, 1911.

This latter installation consists of two series of fourteen rectangular tanks; the cathodes formed in the first series assay, for the reasons given above, 998.7 and are put in again as anodes in the second series, assaying finally 999.7 gold. According to the dimensions given the anodes weigh about 3.35 kg or, for a series of fourteen tanks with eight anodes each, 380 kg, which are worth about $240,000, or $480,000 for both series. The interest on this locked-up capital amounts to $19,200 at 4 per cent per annum.

With the electrolytic tanks of the Geneva Refinery, which yield directly gold 1000 fine and which work with an anodic current density of about 10 amp per square decimeter (as compared with 7.5 amp at San Francisco) the locked-up capital would not be more than $480,000 $\times \frac{1}{2} \times 7.5/10$ = $180,000, representing an interest of $7,200 per year. The saving would therefore be $12,000 per year without taking into account the interest for the baths and the manual labor.

Geneva, Switzerland.

## Superheated Steam on Railway Locomotives

The Midland Railway Company has been making an extensive series of tests with various types of locomotives with the object of ascertaining the efficiency of super-heated steam as compared with saturated steam under the same conditions; and in a paper recently read before the Institution of Civil Engineers Mr. Henry Fowler gave some very interesting statistics which seem to establish the great superiority of the superheated steam; but the author also stated that the Midland Railway Co. had not yet had sufficient experience to be able to give definite figures for costs of maintenance, although everything indicated that they would not be greater than those for engines using saturated steam. Yet he was able to say positively that the wear on the boilers of superheater engines was considerably less than was usually found in locomotives using saturated steam doing similar work; and consequently they could be run for longer periods without being "shopped" and were also a proportionately shorter time out of service. The cost of maintenance was undoubtedly increased by the extra equipment on the superheater locomotive, but he estimated that the saving on boiler repairs would more than compensate for that increase.

The saving effected by superheating, in a series of tests with two similar 4—4—0 engines, each of which had six double runs between London and Leeds, was 23 per cent of coal and 22 per cent of water per ton-mile; and after the superheater engine had run 62,000 miles without "shopping" the consumption of coal and water increased by only 1.5 and 2.8 per cent respectively. Tests with the same superheater-fitted engine against a three-cylinder compound engine showed a saving of 15 per cent of coal and 17.5 per cent of water in favor of the former. Other tests on runs between London and Derby with two engines rebuilt alike in every respect, save that one was equipped with a superheater while the other used saturated steam, gave a reduction of 30 per cent of coal and 34 per cent of water for the superheater. Subsequently in one of the three cylinder compound engines the steam going to the high-pressure cylinder was superheated and a test against an exactly similar engine using saturated steam showed reductions of 25.9 per cent in coal consumption and 22.3 per cent in water in favor of the superheater. No disadvantages were found to result from the high temperature in the hp. cylinder after three months' running.

# The Electric Iron Smelting at Hardanger in Norway

BY JOH. HÄRDÉN

The third and last part of Mr. Oedquist's paper on the above subject has now been published[1] and the following is a review of its content.

The paper concludes: The results at Hardanger have shown that coke *can* be used as a reducing agent in furnaces of this type. But this does not of course permit the conclusion that this particular design of furnace is fully suitable for working with coke as a reducer.

The advantage of using coke instead of charcoal in ordinary blast-furnace practice is partly the lower price of the coke, and also the fact that furnaces for coke firing may be built for very large capacities.

In electric furnaces of the type used at Hardanger, however, the coke does not play such a great rôle as regards the quantity of production; in these furnaces the capacity is depending upon the number and the size of electrodes used, which in turn determine the amount of power applicable to the furnace. Consequently the advantage of larger units when coke is used can be disregarded, and only the lower cost of the coke need to be considered.

Against this stands the fact, as well known, that the use of coke has other disadvantages; for instance, that the coke carries various impurities, especially sulphur. These disadvantages are even more pronounced in the case of electric smelting, where the aim has been, at least up to the present, a quality considerably higher than that of an ordinary coke-blast furnace.

Should, therefore, any gain be obtained by using coke instead of charcoal, it must be possible to produce a material cheaper than charcoal-pig, and even so much cheaper that the disadvantages in using coke are fully counterbalanced thereby.

A furnace type suitable for coke as a reducer must, therefore, fulfill the condition that the production of coke-pig from the same kind of ores is at least not higher in cost than if charcoal is used.

The points which are of decisive importance in that case are: Cost of coke, charcoal, limestone and the electric power, as well as the quantities to be produced in each case.

A comparison is made between the conditions at Hardanger, where coke was used, and at Uddeholm and Strömsnäs, where charcoal was employed; the conditions of the comparisons are held to be rather in favor of the Hardanger works. The first one refers to period III at Hardanger and for Strömsnäs for the time from Oct. 1 to Dec. 31, 1912. The second refers to Hardanger period IV and the results from furnace II at Uddeholm from Aug. 4 to Dec. 31, 1912.

The first comparison shows that the ore used in both cases had a high percentage of iron. At Hardanger such ores as Sydvaranger briquets and roasted "red sand" concentrate was used, while at Strömsnäs ores from Kiruna (A), Tuolluvara and Lerberg were used.

The yield of pig iron was: At Hardanger, 69.1 per cent; at Strömsnäs, 65.38 per cent. Consequently the ore used at Hardanger was richer, but as the Hardanger works used coke, a very basic slag was necessary, which lowered the yield of iron calculated in per cent of total material charged to only 56.4 per cent, while the corresponding figure for Strömsnäs was 61.78 per cent, because charcoal was used at the latter place, wherefore less limestone was required.

At Hardanger 336 kg coke and 330 kg limestone was used, while at Strömsnäs 23.58 hectoliters charcoal (the weight of the charcoal is not stated, but the above figure corresponds to about 65 bushels) and 90 kg limestone, all per ton of pig iron produced.

During the same period the yield of pig iron at Hardanger was 2.01 tons per calculated horse-power year, but as the conditions of the furnace were such that this figure is too low, as only about two-thirds of the available energy could be utilized in the furnace, it is to be assumed that 3.015 tons could have been produced per calculated horse-power year.

The cost of electric power, at a price of 33.33 shillings per horse-power year should in that case be 19.18 shillings per ton instead of 28.76 as stated before. The corresponding cost for Strömsnäs, under the assumption that the same kind of ore was used, giving a yield of 69.1 per cent of pig iron, would be 12.96 shillings instead of 13.69 per ton.

The economic results are clearly shown in Table XI.

TABLE XI

| | HARDANGER, PER III | | | STROMSNAS | | | |
|---|---|---|---|---|---|---|---|
| | Kg. | Cost, per Ton | Shillings | Hectolitre | Kg. | Cost per Ton | Shillings |
| Coke....... | 336 | @ 26/8 | 8.95 | ... | ..... | ..... | ... |
| Charcoal...... | ... | . | .... | 23.58 | ..... | @ -/8 | 15.70 |
| Limestone..... | 330 | @ 5/6 | 1.83 | .... | 90 | @ 5/6 | 0.50 |
| El. power ... | .... | ..... | 19.18 | ..... | .... | ... | 12.96 |
| Sum total... | ..... | .... | 29.96 | ..... | .... | ..... | 29.16 |

When the results of Hardanger period IV and the Uddeholm furnace No. II are compared, it is found that the yield of iron from ore was 58.05 per cent at the former and 58.6 per cent at the latter, while the percentage of iron calculated on total amount of charged material was only 41.65 per cent at Hardanger against 52.9 per cent at Uddeholm.

The ore at Hardanger was Persberg and roasted red sand; information as to the ore used at Uddeholm is lacking, but it was presumably Tuolluvara and Persberg.

The coke consumption at Hardanger may be given as about 385 kg per ton of iron (in reality as much as 441 kg was used during the period), but as no gas circulation was used, it is fair to assume that if such had been employed, the consumption would have been about 336 kg, or the same as in the foregoing period.

The consumption of charcoal per ton of pig iron at Uddeholm was 21 hectoliters (about 57.5 bushels) and 186 kg of limestone, while at Hardanger 678 kg limestone per ton of iron was used.

The yield of pig iron per calculated horse-power year during period IV was 1.87 tons. As no gas circulation was used, it may be assumed that this figure could have been increased to 2.2 tons with the gas circulation (see diagram No. 1) and the calculated cost for electric power would have been 28.22 shillings instead of 33.21 shillings.

The corresponding cost at Uddeholm should, if a similar ore had been used, been slightly higher than

TABLE XII

| | HARDANGER, PERIOD IV | | | UDDEHOLM FURNACE NO. 2 | | | |
|---|---|---|---|---|---|---|---|
| | Kg. | Cost per Ton | Shillings | Hectolitre | Kg. | Cost per Ton | Shillings |
| Coke | 336 | @ 26/8 | 8.95 | | . | | |
| Charcoal | | | | 21 | | @ 8 | 13.98 |
| Limestone | 678 | @ 5/6 | 3.76 | | 186 | @ 5/6 | 1.03 |
| El. power | | | 28.22 | | | | 16.82 |
| Sum total | | . | 40.93 | | . | | 31.83 |

---

[1] Teknisk Tidskrift K. O. B., Feb., 1914.

stated (in Table X), namely, 16.82 shillings instead of 16.66 shillings. The results are shown in Table XII.

In Tables XI and XII, a comparison of results is made with ores of practically the same percentage of iron, and under conditions which are in favor of the Hardanger works, inasmuch as all disadvantages adherent to the use of coke are not considered, yet the comparison of Tables XI and XII shows that for these cases and the prices given the smelting with coke was more expensive than with charcoal.

If all factors, such as they appear in reality, are fully considered, we find that the cost per ton of pig iron in the first case is 9.62 shillings higher and in the second 14.23 shillings higher at Hardanger than in corresponding cases at Strömsnäs and Uddeholm.

If the electrode consumption is considered (although it is stated that only 14 kg was consumed per ton of iron during period IV) we find that the costs at Hardanger are respectively 12.42 shillings and 16.56 shillings higher per ton than at Strömsnäs and Uddeholm. Should all disadvantages experienced when coke was used as stated above be considered the figures for the results at Hardanger would be even more striking; in addition to this comes the question of quality of the material produced, a matter which has not been touched at all so far.

According to Mr. Oedquist's opinion, these unsatisfactory results when coke is used must, on the strength of the above, be due to the type of furnace used, at least in the main points.

That better results could have been obtained at Hardanger, if certain alterations had been carried out, is beyond doubt, but judging from the results arrived at in the Hardanger Works, it is evident "*that the furnace such as it was and was operated at Hardanger must be regarded as not suitable for use of coke as reducing agent.*" (Italics by Mr. Oedqvist.)

Regarding the actual reasons why this furnace type should not work satisfactorily when coke is used as reducer, the author of the paper states that not only is the charge very much more compact and presents greater difficulties for the gases to penetrate, also preventing a good and intimate contact between the ore particles and the reducing agent, but still more important is the fact that the great variations in the electric resistance caused by the setting of the charge in the smelting zone, are very detrimental.

These variations extend naturally to the whole system and influence the power supply in such a way that the average load on the furnace for a given amount of available power is considerably reduced, when coke instead of charcoal is used. A direct consequence of this is that the total production and efficiency of the plant is reduced.

When coke is employed instead of charcoal, a much larger per cent of limestone in the charge, on account of the higher sulphur content, is also required. This, of course, causes a direct increase in cost. Furthermore, the charge is diluted with ballast, so that the percentage of iron in the charge is less, which increases the amount of power required for smelting, or in other words, the production is reduced.

Against this stands the fact that the coke is so much less expensive than charcoal, the question is if these two factors counterbalance each other or not.

It would have been of great interest if the author had been able to give the respective costs on the spot of both coke and charcoal, per quantity required in either case. This would have elucidated the case considerably.

What has been said here refers more or less to all furnaces in which electrodes are used and coke employed as reducing agent.

It also shows clearly that the causes for the unsatisfactory results of the smelting at Hardanger were both many and important, and one must not thereby lose sight of the difficulties and drawbacks caused by the type of furnace employed.

On the contrary, the heavily paid-for experience gained at Hardanger should serve to assist in a more satisfactory solution of this great and important question.

That this type of furnace has rendered good results when smelting with charcoal, but proved a failure when coke was used, should on no account be considered as decisive in the question of using coke for iron smelting in general. We must on the contrary fully realize that if electric iron smelting shall occupy the place in the metallurgy of iron, which it is fully justified to attain, it will be necessary to adopt a cheaper reducing agent than charcoal, such as coke or stone coal.

Our endeavors must therefore be to aim at a furnace type which will permit of the use of an inexpensive reducing agent and yet produce a good and even quality, at a price which will stand the strongest competition.[2]

This concludes Mr. Oedqvist's paper. The causes of the unsatisfactory working at this plant should be clear on the main points if the statements made in Mr. Oedqvist's paper represent all the determining factors. This, of course, it is exceedingly difficult to ascertain, as there are bound to be a number of points, which, taken one by one, appear insignificant enough, but in united effect may turn the balance one way or the other. One cannot be too careful in attributing the failure of a plant of this kind to any one specific cause, since there are so many details, which all require a special study.

It is almost unthinkable that such a large plant, involving so many interests, should have been built without preceding trials on a fair scale under conditions as nearly identical as possible. Several furnaces of this type, as is well known, have been working successfully with charcoal, and if the new plant was to work on coke, it seems that the previous working for a few months on coke with the ores in question in one of these already erected plants would have been money well spent, even if it had been necessary to somewhat alter the prevailing arrangements at these furnaces.

Again, if such trials have been carried out, although not mentioned in Mr. Oedqvist's paper, the results obtained, if published, would be of great value as a comparison, and might help to clear up the matter.

It may be argued that the older furnaces mentioned belong to different concerns, who had no interest in the welfare of a new rival plant. But even so, the possibilities of using coke instead of charcoal should have been a strong inducement to carry out such tests, since, as already stated, the charcoal is becoming more and more scarce every year.

As regards some of the difficulties in using coke when smelting electrically in a shaft furnace, the present writer has had opportunity to encounter a few. When carrying out preliminary tests for the Electric Tin Smelting in Cornwall, related in METALLURGICAL AND CHEMICAL ENGINEERING, September, 1911, and elsewhere, a modified kind of shaft furnace was also tried. For certain reasons, coke of various grades was tried in this as a reducing agent. But it was soon found that the results obtained did not encourage a further use of coke under the same conditions. The average working voltage went down as low as 32 to 35 volts, with a corresponding increase of the current, which caused overheating both of transformer, electrodes and other parts. If the voltage was increased forcible arcing took place followed by a volatilization of metal and general disturbance of the running.

---

[2] Correction in the translation in Teknisk Tidsgrift: In Table IV the figure 44.6 should read 41.65. The electrode-diameter given as 500 mm, should read 600 mm in all three plants.

Also, although the total input of power was held at about the same figure as before, the production went down considerably. It was found almost impossible to obtain a satisfactory slag; it was either too viscous or contained a too high percentage of metal.

Instead of "doctoring," however, with the furnace, the use of coke was simply abandoned after a few smelts, since other more suitable reducing agents could be obtained at almost the same price; even had this not been the case, the increased costs when using coke would have justified a more expensive reducing agent.

It shall not be said that coke *could* not be used for the purpose; with correspondingly larger electrodes and allowing for a higher power consumption it is quite feasible that coke could have been successfully used. But the type of furnace *alone* was not the chief fault; in fact, the writer believes that with suitable conditions generally and a different method of working, the same furnace with somewhat larger electrodes would have worked very well with coke, if tolerably free from sulphur. The conditions, however, were such that the use of a more suitable reducing agent became more economic.

Variations in voltage, as stated by Mr. Oedquist, were noted in this instance as well, but in no cases to any such extent as mentioned. On no occasion was a higher tension than 65 volts per phase required at the furnace, even when starting up from cold; though the furnace was, of course, very much smaller, which may to a certain extent account for this fact.

The use of coke, in that instance, had one redeeming feature: the electrode consumption was somewhat smaller, probably because the well conducting coke piled up round the carbons and acted partly as secondary electrodes. But the difference was very slight, and had no appreciable influence upon the economic result, since the heavier slag sometimes formed crusts on the electrode stumps, which made it difficult to use up the butt ends.

One of the chief drawbacks, however, was the low resistance of the coke, which caused the increase in current and a decrease in voltage, also altering the zone of reaction.

Reverting to the iron smelting, Dr. Lyon says:[3] "I have already mentioned the relative value of coke and charcoal as a reducing agent in the electric furnace, that we need more information along this line, and that we expect to get it. It is to be remembered that it has been only two or three months since the plant at Hardanger in Norway shut down because they could not use coke as a reducing agent. In California they have found out the same thing; that is, they cannot use coke alone, due to the high conductivity of the same.

"It is also to be remembered that the iron furnace is a resistance furnace, that the heat is created by the resistance which the charge offers to the current, and that as coke is a better conductor than charcoal, less resistance is offered by the charge when coke is used as a reducing agent, and hence the current consumption per ton of metal produced is greatly increased. However, as before stated, we still need more information on this subject and hope very soon, as a result of some experimental work which we are contemplating, to secure the same."

These remarks corroborate the observations made above, and it will be interesting to see to what result further researches will lead. Some metallurgists suggest to abandon the use of a shaft-furnace altogether; although this would simplify the work in the smelting zone and lead to a simpler design generally in one way, it is difficult to say if the sacrifice of the pre-heating of the charge in the shaft is justified on this account.

Other remedies may be and will be found; so much work and capital has already been spent on this problem that it seems likely that it will be satisfactorily solved in a not too distant future.

## The First Chandler Foundation Lecture

One of the most interesting features of the celebration of the fiftieth anniversary of the Columbia School of Mines on May 29 was the inauguration of the Chandler Foundation lectureship founded in honor of the only surviving founder of the School of Mines, Dr. Charles F. Chandler. The first Chandler Foundation lecturer was Dr. Leo H. Baekeland.

To both a grand reception was given when they appeared in the large and well-filled lecture hall of the Havemeyer Building. Dr. Chandler spoke charmingly of olden times and touchingly of his former colleagues, especially of Eggleston, and then introduced the lecturer of the day, Dr. Baekeland. The title of Dr. Baekeland's lecture was "Some Economic Aspects of Industrial Chemistry."

As Dr. Baekeland's brilliant address dealt in crisp, epigrammatic form with almost anything within the sphere of industrial chemistry, it is plainly impossible to do it justice in abstract. All we can do here is to sketch briefly the leading ideas of the lecture. Publication of the lecture in full is reserved for a later issue.

Dr. Baekeland emphasized the interrelation between chemistry and civilization and showed how industrial chemistry had developed in different directions and at different times in France, England, and Germany. A large part of the lecture dealt with the fixation of atmospheric nitrogen—"en epos of applied science," the economic problem and its different technical solutions—production of nitrate, cyanamide, nitrides.

Many chemists regard a process too much from the narrow viewpoint of the chemical reactions involved and overlook all other considerations. But such "secondary" considerations are often of decisive importance for the commercial success; for instance, the cost of transportation.

This was shown in great detail by Dr. Baekeland by the example of the Leblanc soda process. A very well-worked out process, known in all details, brought to perfection, it is now in languishing agony succumbing to "secondary" considerations. The chlorine industry, its present status and probable future were discussed.

The importance of cheap power in the electrochemical industries was pointed out, but it was also pointed out that cheap power is not everything. The cost of water-power is high in the United States as compared with Norway; further, while the Norwegian water-powers are close to the ocean, the American water-powers are not. The possibilities of gas power were discussed. Dr. Baekeland then turned to agriculture which is "but a branch of industrial chemistry," and to the possibilities of photochemistry.

The completion of the Panama Canal shows what a government by engineers can do, as against a government by politicians. We have still too many men of yesterday. What is needed are men working not for to-day, but for to-morrow.

After the close of Dr. Baekeland's brilliant lecture President Butler presented in a felicitous little speech ("that the punishment may fit the crime") the first imprint of the Chandler gold medal to Dr. Baekeland.

# Chemical and Industrial Applications of Mechanical Refrigeration

By H. J. Macintire

In the foregoing articles an attempt has been made to describe only the cycle of the refrigerating medium. Before proceeding to the direct application of mechanical cooling to industries it is wise to consider certain general details, such as the use of a brine (or cold air), of direct expansion, the operating back pressure, etc.

Generally speaking it is more advantageous to use direct expansion. By this is meant that the liquid refrigerant is permitted to pass directly to the cooling system, where it vaporizes and returns to the refrigerating machine. As the condenser pressure is usually about 150 lb. gauge, the liquid refrigerant is carried to the expansion valves in the refrigerating coils automatically (hydrostatically). The conveying pipe can be relatively small and need not be insulated unless the pipe has to be carried through warm pipe shafts or rooms. The return pipe, however, has to be insulated and has to be relatively large. Pressure drop in the suction return line (the difference between the cooling pressure and the back pressure on the compressor) usually must be kept below 5 lb. and this varies directly as the length of the return line, and inversely as a function of its diameter. There are also possibilities of serious breaks in the pipe line, which may be injurious to the goods being cooled, or to personal safety.

With direct expansion it must be remembered that the refrigerating machine must operate when cooling is desired. With a brine or cold air a cooler is placed in some convenient place (usually the engine room itself) and the brine or air is circulated over the cooler and into the rooms to be cooled. This circulation is a forced one, requiring (except in special cases) the continual use of power for this purpose.

Thermodynamically, there is a loss of efficiency in the method, especially where brine is used, on account of the second system of cooling coils. Usually there is required from 4 to 5 gal. of brine per minute or about 500 cubic feet air per minute per ton of refrigeration.

With brine there is a very decided advantage in not having to use the refrigerating machine all the time, refrigeration being obtained by the circulation of cold brine, previously cooled.

In certain industries, where "peak" loads occur a smaller (and therefore cheaper) refrigerating machine may be installed in conjunction with a large brine storage tank—brine being cooled by continuous operation of the refrigerating machine—the temperature of the brine being lowered during the periods of small demand for cooling and raised when the demand on the system is greater than the normal capacity of the machine.

The operating back pressure used on the compressor must not be too low. A consideration of part 1 of this series will show that the operating back pressure determines the temperature at which refrigeration takes place. A decrease of back pressure decreases this refrigerating temperature and the refrigerating capacity of the machine, but increases greatly the displacement of the compressor per ton of refrigeration and the power required from the prime mover. A regulation of the back pressure to suit the refrigerating temperature is therefore desirable.

## Cooling of Liquids

One of the principal uses of refrigeration is in the cooling of liquids, such as water for drinking purposes or for steel tempering, beer wort, oil, milk, brine, etc. These are usually the simplest of all refrigerating problems, as the refrigerating "duty," in tons of refrigeration, is obtained by the product of the pounds of liquid cooled per minute, times the specific heat, times the number of degrees cooled in degrees Fahrenheit, divided by 200.

The specific heat is frequently a variable, as in brine, beer and oil refining The latter case as well as the abstraction of naphtholene from varnish oil, has another detail which must be considered; namely, the congealing and freezing of a solid which is later separated from the oil by means of a filter press—paraffine in the case of mineral oil—and accurate calculations should allow for the latent heat of fusion of this content.

## Cooling of Air

Frequently, in the process of cooling of the fluid, whether it is in the soap manufacture, or the separation of gasolene from natural gas, there is another factor entering into the computation; namely, the latent heat of condensation or of fusion. This is particularly true in the cooling of air—one of the most common applications of mechanical refrigeration to chemical industries—such as the dry blast for blast furnaces, the manufacture of gelatin films, chocolate, etc.

It must be remembered that atmospheric air contains water vapor—an amount depending on the temperature and humidity of the air. As a rule, a lowering of the air temperaturs of 10 to 15 deg. will bring the air to this condition of saturation and still further decrease in temperature will mean the precipitation of moisture, requiring nearly 1000 B.t.u. of refrigeration per pound of water condensed.

Frequently, the air is cooled below 32 deg. Fahrenheit (especially that air near the cooling pipes) and the condensed water vapor is also frozen on the cooling pipes; the frost increasing in thickness until the pipes became practically useless for further cooling until they may be defrosted.

The arrangement allowing frost to freeze to the pipes is obsolete for large installations running continuously, for several reasons. First, there is required considerably more refrigeration in order to freeze the condensed moisture, and second, there is considerable variation of duty obtained from the pipes as well as trouble and expense in defrosting.

A better value for the coefficient of heat transmission and an elimination of the frost is obtained by wetting the cooling coils continuously with some convenient liquid—such as brine. The brine is allowed to fall from one horizontal pipe to another, and finally to a cold basin where a pump raises it up to the top of the coils again. The brine keeps the pipes continually wetted, and absorbs the condensed water vapor—the latter diluting the brine by a like amount.

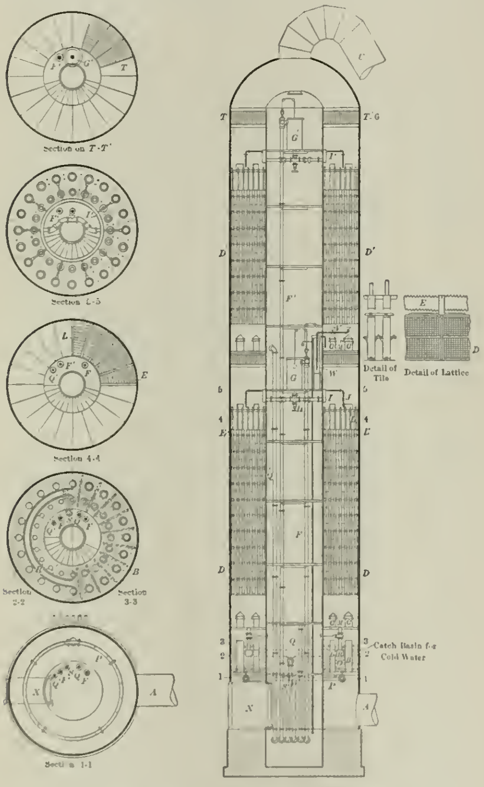
The brine must be strengthened by means of a concentration apparatus like that used in the so-called dry-blast process of the Carnegie Steel Company, or by the addition of more salt.

The illustration shows the former—designed for the cooling of 40,000 cubic feet of free air per minute to 25 deg. Fahrenheit in two stages. In the first stage the air enters under atmospheric conditions and at the base of the tower and is cooled to 39 deg. Fahrenheit, in contact with *water-wetted* pipes. The air leaves this stage at 39 deg. Fahrenheit and contains 35 grains of moisture per pound. In the second stage the air comes in contact with the *brine-wetted* pipes in the upper part of the tower and leaves the tower finally at 25 deg. Fahrenheit and with 19½ grains of moisture per pound of dry air.

A calculation for such a tower for, say, a typical summer day in Pittsburgh, would be for air at 90 deg. Fahrenheit and 86 per cent humidity using a psychrometer chart for the calculations:

(1) To cool 1 lb. air from 90 to 84.8 (dew point) .......................... 1.33 B.t.u.
(2) 84.8 deg. to 25 deg. F. and condense moisture ........................39.8
(3) To cool condensed water for an average temperature of 26.4 deg. F....00.7
41.83

The specific volume of air at 90 deg. and 85 per cent moisture is 14.47 cubic feet.



COOLING OF AIR IN TWO STAGES

Total number of pound air cooled per minute is $\frac{40000}{14.47} = 2764.$

Total refrigeration = $\frac{2764 \times 41.83}{200}$ = 578 tons refrigeration.

It may be added that the dry blast requires considerably less power in the blowing engine than does the common system (as well as a smaller piston displacement) and that the uniformly low water content in the air gives a much cheaper pig iron as well as of better quality of production.

### Shaft Sinking

As a final application of refrigeration may be given that of shaft sinking, excavation or foundation work in ground of boggy or partially fluid condition. Here it is necessary to freeze the vicinity of the work to be performed in order to obtain a zone of sufficient strength to withstand the inward pressure as soon as excavation is commenced.

In shaft sinking of much depth the main difficulty is to drill the holes—within which the brine pipes are placed—sufficiently parallel to each other. Should the drilled holes be out of plum the resisting wall of frozen material may give way. The brine tubes are frequently 4 in. in diameter and are placed about 3 ft. apart. The depth of practical excavation is usually 400 to 500 ft., but depths of 1300 ft. have been attained. As a rule $MgCl_2$ brine only is used on account of its stability in solution as well as on account of its ability to carry low temperature (— 15 deg. F. to — 20 deg F.) without freezing. The time of freezing varies from 3 to 12 months, depending on the size of and condition of the work.

A knowledge of the composition of the material to be frozen must be had if accurate calculations of the refrigeration duty are to be made. The specific heat of dry minerals is nearly 0.2 and the density about 1.8, whereas the water content may vary over a large range. It is usual to figure on a frozen section of 3 ft. on the inside and 1½ ft. on the outside of the circle of brine pipes and a cooled section of about 5 ft. thickness on each side of the frozen area. The calculation of the necessary refrigeration requires a consideration of the cooling of the solids, cooling of the liquid content to 32 deg. F., freezing of this water and finally the cooling of the ice formed. A good rule is to allow an average of 85 B.t.u. per hour of refrigeration duty per square foot of brine pipe cooling surface and to allow about 33 per cent for losses.

University of Washington, Seattle, Wash.

## Copper in Scotland

The high reputation of the British Geological Survey for completeness and accuracy has been impeached through the accidental finding by a boy, innocent of geology, of a piece of copper-bearing ore on the Otter estate in Argyllshire. It appears that the youth found the lump of ore more than eight years ago, and kept it until some two years ago, when he showed it to a mining expert in Glasgow, whose investigations have resulted in the discovery of three fairly good lodes at Kilfinan, Inveryne and Tighenraed.

The Kilfinan lode was found in exploring a barren field which no amount of manuring would induce to grow even a crop of grass and which local tradition described as being under a curse. It is the best of the three finds and is being worked by the Otter Copper Company, Ltd. Shortly after work was begun a vertical vein of copper carbonate, some 2 in. thick, was found; and about 40 ft. further on this vein opened out to a compact mass of gray sulphide from 1 ft. to 2 ft. thick.

The authorities of the Geological Survey have naturally evinced great interest in the proceedings, and have deposited some rich specimens of ore in the Geological Museum at Jermyn Street. Until the discovery was made it was assumed that metalliferous ores did not exist on the eastern side of Loch Fine to the same extent as on the western side; and the geological map shows no copper in that district. So far the mining operations have resulted in 266 tons of the best ore being smelted with an average yield of 15 per cent, together with about 70 tons of dump which gave 3½ per cent. The mines are in the immediate vicinity of tidal waters and there is every facility for economical working and transport.

# Notes on Unit Cost-Keeping in Metallurgical Work

BY JUSTIN H. HAYNES

In the last few years scientific management has become a live issue in all lines of industrial work. Many attempts have been made to adapt the new ideas and systems to mining and metallurgy, but with very little success up to date. Usually the number of clerks required to execute the efficiency idea is prohibitive. The route clerk, the motionstudy clerk, the various supply clerks, etc., almost lead a manager to believe that more men are necessary in the office than in the works.

In all so-called efficiency systems, or schemes for scientific management, great stress is laid upon the necessity of some plan of payment by means of bonuses, but very little information is given as to how this should be done. Time-studies are dwelt on at great length but do not seem to give the desired result. Time-studies are spasmodic and unreliable: spasmodic, because they are made only when the idea so strikes the executive in charge; unreliable, because they usually are made for very short periods of time, giving results which are sure to be either above or below the average. The only time-study that is absolutely reliable of work being performed, is the average of the work accomplished over a long period of time such as a month or a year. Time-study should come later, and will show the small leaks in detail.

## Cost-Keeping Versus Bookkeeping

The whole object of the efficiency movement is a greater production for a less sum of money. This makes cost-keeping one of the most essential points of the system. The mistake usually is made of allowing the bookkeeper or accountant to devise the cost system. Bookkeeping is a function of accounting. Cost-keeping is a function of engineering. The objects of the two are entirely dissimilar; they are looked at from entirely different points of view, and it is next to impossible to combine them. The bookkeeper and accountant must show information of value to the manager, directors and stockholders. He must show the debits and credits, resources and liabilities; he must show the difference between total cost and total income; in other words, he must show whether the property is making a profit or is losing money. In this way he is able to guide the directors as to how much money they can spend on betterments, what dividends can be declared, and similar questions. Cost-keeping is for the engineer or executive and shows in detail the cost of each department and what has been accomplished for the money spent. It is without value unless it aids him in controlling the working details of the property.

Accountants say that cost-accounts must be tied to the total actual expenditure in order to be of any value. Engineers say that cost-accounts must be tied to the work accomplished in order to be of any value. The latter view must necessarily be correct; but preferably, the cost-account should check both ways. Cost-keeping is not an exact science, for large errors creep in at the very basis of the data. A man working eight hours will have his time distributed over, say, five or six departments, and it is impossible to obtain the exact time he spent in each department. This reason alone must make cost-keeping merely a very close approximation; and the fact that an item will vary at the end of the month a few dollars more or less from the actual sum paid out by check does not decrease its value to the executive.

## What the Engineer Wants to Know

The point the engineer does have to know is how much was accomplished for each dollar spent, and usually the books do not take accomplishment into consideration in any way. In fact, cost-keeping as handled by the bookkeeping force is an attempt to fulfill the growing desire for detailed cost, but does not furnish the information that an engineer versed in cost-keeping would give. To know the exact cost of a certain piece of work, and to be able to compare it with other costs for the same work, it must be reduced to a unit basis. The meat of the whole subject lies in the unit system of cost-keeping, and in what unit is used.

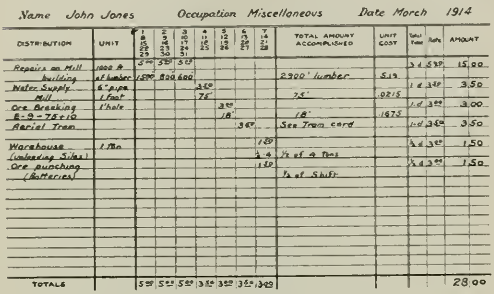
For example, if a new roof is put on a mill building the accountant is interested primarily in crediting the carpenter with one day's work at so much, and later seeing that it is balanced by the debit of the day's pay given to the carpenter. The engineer does not care primarily about the man receiving his pay, but is interested in knowing how many squares of roofing were put on for $1. The engineer must know this in order to compare the cost of this roof with the cost of other roofs under similar conditions, and whether the mechanic was working efficiently or not. The stockholder or director, and therefore the accountant, is not interested in how much this roof cost per square, but is interested in knowing the relation of the total improvements or repairs to the total operating expense. Therefor, in a metallurgical mill where the costs are finally converted into cents per ton, this roof will be classed as repairs amounting to so many cents per ton. Your engineer could not tell from the fact that general repairs on this roof amounted to $1\frac{1}{2}$ cents per ton of ore treated, whether the work was efficiently done or not, but if he knew the cents per square for putting on the roof he could then judge of the efficiency of the work. Thus the value of different units becomes very apparent. If a carpenter puts a new stairway in a mill, which cost unit will best serve the engineer — cents per ton of ore treated, or dollars per thousand feet of lumber? It is unfortunate that most of our cost-keeping systems are inaugurated by accountants.

It is a comparatively easy matter to keep track of the amount of work accomplished per day by miners, trammers, etc. It is not so easy to keep track of the work accomplished by men on shift in the mill, such as battery men, cyanide men, crusher men, etc. This is due to the fact that the latter are on duty merely to watch machinery in operation and see that the wheels keep turning. Therefore special methods have to be introduced for such cases. To keep track of all men at work, with the exception of men on shift, requires merely that the records, in addition to showing the number of hours worked and the rate of pay, must show also the amount of work accomplished, based on some unit.

## Card System of Unit Cost-Keeping

The cards illustrated herewith show how this can be done in the ordinary routine of office work, without requiring extra clerks. After these records have been kept for a number of months, showing the average cost per unit for each line of work, standards can then be obtained from which bonus systems can be very easily calculated, following any of the standard plans desired.

A very important card is that illustrated by Fig. 1, which shows in detail the amount of work accomplished by each man, with cost of work done, and readily allows the latter to be converted into unit cost for each line of work. As illustrated, the card is very satisfactory, but slight changes in its form may be desirable under special conditions. These cards are usually made 5 in. by 8 in., to fit standard filing systems. Each card represents a period of seven days, and four or five cards are required for each man per month. It will be noted that the days of the month are arranged in the style of a calendar, with a check mark opposite the week for which the card is used. By this system a card is complete at the end of every seven days; and if the weekly system of reports is used, the week will always end on the 7th, 14th, 21st, 28, and, excepting February, on the 30th or 31st, giving in all cases, except February, one week containing two or three days. The distribution is left blank on the printed card so that in complicated work any distribution can be inscribed, thus extending the system to as fine detail as is necessary.



Name John Jones  Occupation Miscellaneous  Date March 1914

FIG. 1—CARDS FOR UNIT COST KEEPING

The specimen card illustrated is filled in to cover different rates of pay, different units of accomplishment, and a wide variety in the lines of work performed. Each distribution is allowed two lines. On one of these lines the time is kept as in a standard time-book, except that the time for any certain day is entered in dollars and cents instead of hours. The second line of the same distribution is used for the amount of work accomplished. In this way no time-book is necessary as the cards form the time-book for one week. If it is desired that one card should report a month's work the same plan can be followed except that a larger card is required. The two lines given on each distribution allow for main-distribution, together with a line for sub-distribution.

This card allows the efficiency of each man to be readily calculated; and an average record for several months will give a very clear comparison of his work with that of other men on the job. At the same time it takes practically no more office work to keep a card of this kind, than to keep his time without a unit system of accomplishment. In the case of gang-work in which, say, six carpenters together put up six thousand feet of lumber in one day, it is very difficult to tell the amount each man has accomplished by himself, as his card must necessarily show one-sixth of six thousand feet, or one thousand feet, erected. This is not detrimental to the system in any way, as his unit cost will then increase or decrease with the unit cost of the gang; and the changes in the gang, which are certain to occur from time to time, will give a line on the man's efficiency, even though his work is greatly complicated with that of other men.

FIG. 2—CARDS FOR UNIT COST KEEPING

Figures 2, 3 and 4 show another form of card which is very convenient, as it can be adapted to practically any type of work. As illustrated they are used entirely for checks on the cost of special work, and do not give the exact figure of efficiency for any one man. Nevertheless they are very valuable to the engineer or superintendent as a check on his costs. Fig. 2 refers to a gang of men erecting Dorr Thickeners. This is a card obtained from actual practice, and shows the increased efficiency of a certain gang of five men in erecting these machines. As will be noted the first machine cost $84.75 to erect everything above the foundation joists, including machinery. After completing the first, the gang immediately went on to the second tank and then to the third, showing an increased efficiency as they obtained more experience in erecting the tanks under these conditions. Fig. 3 indicates the same thing, that is, increased efficiency as the men "get into the collar."

REMARKS. Stamp stems bent in fire

FIG. 4—CARDS FOR UNIT COST KEEPING

### Eliminating Incompetent Men

Fig. 4 shows the cost of straightening stamp stems that were bent in a fire. The costs in this case were bound to fluctuate more or less with the amount of work necessary to straighten the stems. But there is one point that looms up in a very remarkable manner on this card. It will be noted that on October 10th a man lettered "c," whose wage was $3.00 per day, evidently caused an enormous increase in the cost of that day. While the average for the entire time was $2.81 per stem, nevertheless on the day that "e" worked the cost jumped to $6.73 per stem. On investigation it was found that "e" was somewhat of an agitator and decidedly a hard man to get along with. The natural conclusion from this card is that wherever "e" is working he not only accomplishes practically nothing himself, but interferes with the other workmen. It probably would be unjust to discharge him on the basis of this one card, but by switching him around to other jobs and finding the same thing to be true in all cases, it is certainly of vital importance to get rid of him.

These cards, as represented by Figs. 2, 3 and 4, may be used also for checking the work of a certain man; in making time-studies of a certain operation; or in keeping separate certain distributions. These cards are not necessary to a successful system of cost-accounting by various units, but are found to be a great convenience for all lines of special work. If these cards are kept for a period of several months and a file made containing several hundred cards, the information contained thereon will be of great value and extremely interesting.

It is not claimed that these cards are a cure-all for cost-keeping accounts, but the article is written with the primary intention of showing that a cost system must contain both the amount spent and the work accomplished, in order to be of any value to the operator in handling his work efficiently.

Denver, Colo.

## The Construction of the Blast Furnace Stack

By J. E. Johnson, Jr.

In the construction of the blast furnace the conditions to be met are diverse and to some extent conflicting. The efforts to meet these conditions have been almost innumerable, and types of construction of the most various kinds have been used for almost all portions of the furnace. These conditions we may proceed to outline.

### RESISTANCE TO TEMPERATURE

Resistance to temperature is necessary to some extent throughout the furnace, but particularly in the hearth and bosh. The temperatures in these regions in the days of cold blast furnaces were moderate, probably around 2200 to 2400 deg. Fahr., and were resisted with some success even by natural refractories such as sandstone, which sometimes was used for the bottom and for the lining of the hearth and bosh of furnaces, even in coke practice, within little more than a generation.

But with the development of the furnace in the direction of greater output, and the more accurate control of the quality of the metal produced, the requirements have steadily grown more severe. Temperatures in the hearth and bosh in coke practice now probably range from 2500 to 2800 deg., these being the temperatures of the iron and slag as they come from the furnace, but it is almost certain that even higher temperatures exist around the tuyere zone. Probably 3000 deg. is not far from the working temperature prevailing in that zone in many furnaces. This approaches the temperature at which all materials lost a great portion of their resistance. If they do not melt they soften and are easily deformed or abraded.

### RESISTANCE TO CHEMICAL ACTION

The lining of the blast furnace is probably exposed to more diverse chemical conditions than that of any other apparatus in industrial use. Iron itself, particularly before it is completely carbonized, when molten is exceedingly active chemically and will dissolve or react with almost anything with which it comes in contact, especially substances in their elementary condition.

In the early days when sandstone was used as a refractory slags were relatively neutral—that is, they were what would now be called very acid. The requirements were then not nearly so severe in the matter of desulphurization, and as a consequence not much more lime was added than enough to make a fusible slag. But as the demand for a purer product has grown, more and more base has been added to the slag until now its chemical activity in most cases is intense. Few materials with which it comes in contact can long resist its solvent action unless protected by water-cooling and so kept below the temperature at which they can be dissolved.

As we go further up in the furnace we come to the zone in which the cyanides resolve themselves into different chemical compounds of great chemical activity in consequence of their composition and their nascent condition. We have here also an atmosphere consisting almost wholly of nitrogen and carbon monoxide at nearly a white heat initially, which gradually declines as the top of the furnace is approached. The reducing power of carbon monoxide under these conditions is enormous and is reinforced by the presence of incandescent carbon itself in the bosh of the furnace. Therefore, any metallic oxide in the lining which is subject to reduction by either of these agencies would be immediately reduced with consequent destruction of any refractory of which it composed a part. It is probable that many mysterious cases of bad results with fire-brick in the early days of their manufacture were caused by the presence of iron in them, which being reduced by the action of the furnace caused a disintegration of the brick and the early destruction of the lining.

The fume of blast furnace gas which gives the white color to the waste gas from a hot working furnace contains an appreciable quantity of soda and potash; these are liable to be precipitated by the decreasing temperature toward the top of the furnace, and to have a highly solvent action on the silica of the lining when this happens.

When zinc or lead, particularly the former, are present in the charge, even in almost infinitesimal quantities, they are vaporized and have a variety of actions on the lining which is almost incredible to one who has not torn out linings subjected to these conditions, as I have many times done. As an instance of the peculiar actions which this substance has, it may be illuminating to describe what I once saw in the bosh of a furnace blown out for repairs to the upper lining, the bosh being good and left intact.

The furnace was blown down so low that the stock had been burnt out below the level of the tuyeres, and crawling in through a cooler opening as soon as the little material remaining in the hearth could be cooled down sufficiently, I was astonished to see what looked like little stalactites, yellowish white in color, varying in length from two inches to six or more, and about a quarter of an inch in diameter at the base, standing up all over the bosh wall. When touched they fell to pieces and it was with great difficulty that some specimens were taken out whole. They were hollow, with walls only about as thick as wrapping paper, and very light and flocculent. Careful examination showed that they were the oxide of zinc which had been contained in the brick work of the bosh, presumably in some sort of state of solution, until after the pressure of the blast had disappeared. The oxide had then exuded, or more properly perhaps I should say "sublimed" out of the brick into the solid condition, and, being carried upward by the air let in at the tuyeres to cool off the furnace, it formed these little stalactites.

In tearing down the brick outer walls of the older types of furnaces I have found large lumps of crystals of silicate of zinc in cavities in the lining at a distance of four or five feet from the nearest point to the inside of the furnace.

I have seen bricks taken out of the old lining apparently perfect in size and shape but somewhat dark in color. When lifted these would be two or three times the weight of ordinary bricks and if measured up carefully would be found to be half an inch larger in each dimension than the original brick from which they had grown. These were saturated with zinc oxide, which had swelled them as a whole without the least sign of cracking, the bricks being firm and, if anything, stronger than in their natural condition.

These instances are mentioned only to show the vast variety of chemical actions which the lining of the furnace must resist.

### RESISTANCE TO ABRASION BY THE STOCK

About one-half, by volume, of the charge of the furnace in almost all cases is coke, one of the most highly abrasive substances known. In practically all cases also limestone is added to the charge in the condition of lumps sometimes of the size of a man's head or larger, but more generally crushed down at least to go through a 4-in. ring. The balance of the charge is made up of ore which varies from the soft condition of a plastic clay to the condition of one of the hardest of the common rocks, according to the variety. These materials are put through a modern furnace 90 ft. high, at the rate of something like 1700 or 1800 tons in twenty-four hours. The limestone and the ore as they approach the hotter zone are softened if not reduced to powder by the action of the gas upon them, but the coke remains firm and hard until it is burnt up at the tuyeres.

The abrasive action of such a mass of material even at atmospheric temperature would be considerable, but when it is remembered that in the lower portion of the furnace temperatures prevail which are above the softening point of any material available, it is obvious that the abrasion by the descent of the charge alone must present a problem to be reckoned with.

### RESISTANCE TO ABRASION BY THE GAS CURRENT

The velocity of the gas through the shaft is exceedingly high, probably higher than is realized by those who have not actually estimated it. I believe in ordinary modern practice it is never less than 3000 ft. per minute, and more probably double that. This gas is necessarily filled with fine particles of material from the stock, which is in a constant state of agitation due to its descent, so that the fines are swept out of it almost as chaff is separated from wheat. These fines are picked up and carried by this great volume of gas moving at this high velocity. Most of the particles impinge on the solid stock, but many of them strike the furnace walls and exert thereon the action of the familiar sand blast. In this case also we must remember that the resisting material, at least in the lower regions of the furnace, is softened by heat so that much of its resistance is gone, and it becomes evident that we have here a form of destructive energy whose effects cannot be ignored.

### RESISTANCE TO PRESSURE

It is absolutely necessary that the furnace be gas-tight in the same way, and as nearly as possible to the same extent as a good boiler is steam tight. The pressures, it is true, are not as high as modern boiler pressures, but they range from 10 to 30 lb. per square inch in modern practice, probably averaging in Lake ore practice around 15 lb.

The effect of pressure in promoting reaction, especially when gases are concerned, and its effect in giving density and carrying power to the gas currents, are probably factors in the situation, but the principal point is that if this pressure be not resisted at every point gas will find the weak spot, and, traveling through it, will carry heat and chemical action to assist the destructive effect of the pressure. The pressure-resisting quality of the structure comes from the steel shell outside the lining, but this is quickly destroyed if the conditions prevailing within the furnace proper strike it, and with its destruction the whole structure fails. For this reason resistance to pressure is one of the prime conditions to be met.

Had the builders of those tiny furnaces which dotted the central Eastern states in the first half of the last century been shown these formidable specifications in advance of having practical knowledge of the subject they would undoubtedly have thrown up their hands and ceased all efforts to meet such apparently impossible conditions. But, as a matter of fact, they had not the disadvantage of this knowledge, for disadvantage in their case it would have been, since the practice to which they were accustomed involved difficulties constituting only a fraction of those outlined above. This was due to the lower temperatures and the lower rate of driving, with its reduction of abrasion both by gas and by stock, and perhaps most important of all they did not dream of such pressures as we now consider right and proper.

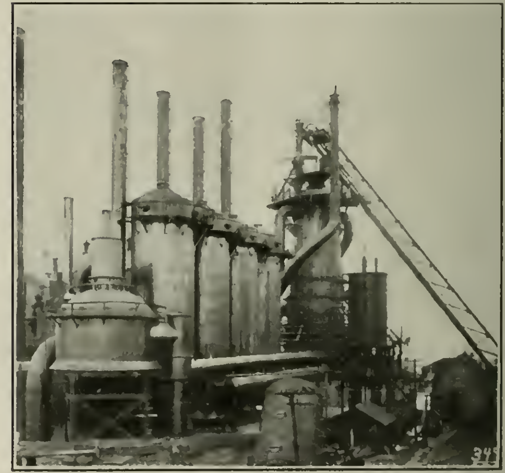

FIG. 1—MODERN BLAST FURNACE STACK WITH STOVES AND DUST CATCHERS. BUILT BY WILLIAM B. POLLOCK COMPANY

In happy ignorance, therefore, of the conditions which their successors would have to meet, they built stacks of stone, truncated pyramids, one side of the base almost as long as the stack was high. In the earliest days all these were built, as I have already described, against and into a hill. Only one tuyere was used. No distinction was made between supporting structure and lining. The stack was simply a truncated pyramid 20 to 40 ft. high, with a hole some

6 or 8 ft. in diameter through it, hardly different from a square chimney with a round flue, except of more squatty proportions. In one side was an archway into the stone work which gave access to the single tuyere and the fore-hearth which I have previously described.

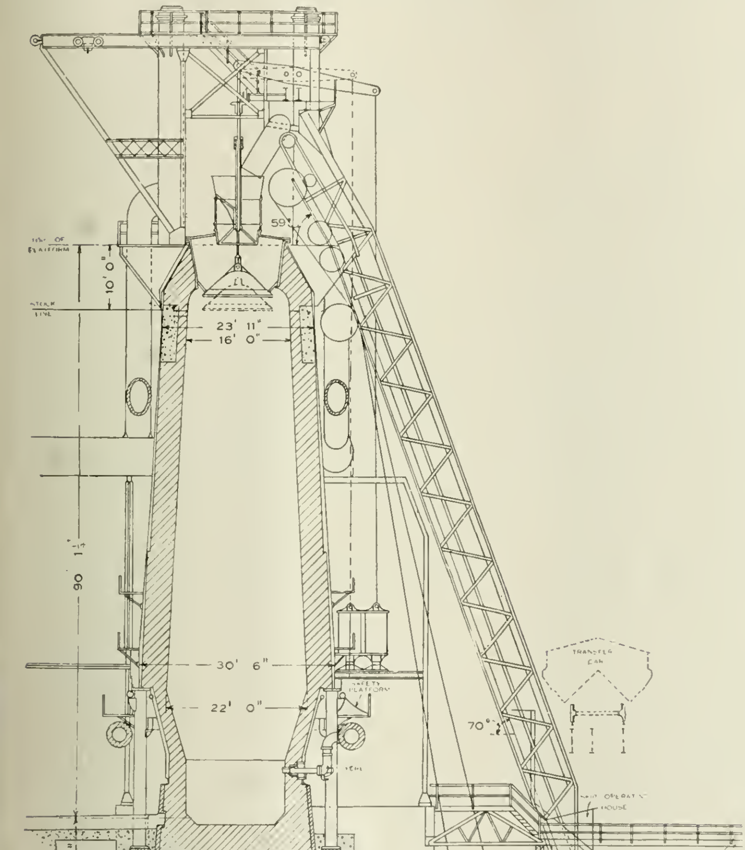

FIG. 2—VERTICAL SECTION OF "A" FURNACE, BETHLEHEM STEEL COMPANY

This simple pile of masonry resisted the pressure of the blast, the heat of the combustion, the abrasive action of the stock and the chemical action of its heterogeneous contents.

The gradual increase in output from those days to our own brought changes in construction, and these in turn permitted greater outputs which again required other changes of construction, and so, with each successful step helping toward the next, and with slow, painful and costly progress we have passed from those primitive conditions to those prevailing to-day.

Two of the earliest changes were the substitution of fire-brick for the lining of the stack and the provision of an archway in each side of the structure with a tuyere in each arch instead of only one. More probably in many cases three of the arches were used for tuyeres; in the fourth the tuyere was left out in order to make room for the fore-hearth, tapping hole, etc. Gradually as the proper shape of the furnace was evolved the hearth structure became separated at the base from the piers of masonry which supported the whole stack, and finally it became evident that it was desirable to increase the distance between these so as to provide greater access to all portions of the hearth. In course of time also the stone stack with its binders of hewn timbers gave way to a brick stack banded with flat bands like a tank, the structure passing from square to round in its exterior shape, the lining being of fire brick and fully differentiated from the stack proper.

About 1860 this structure was superseded at one of the Lake Champlain furnaces by a shell riveted up of plate iron standing on cast iron columns, the prototype of the structure used to-day and lined with fire brick.

The photograph of a modern furnace is shown by Fig. 1. The stack is at the right. A section drawing of another but similar furnace with its hoist is shown in Fig. 2.

It will be seen that there is a foundation of concrete 13 ft. below the ground level and 39 ft. in diameter, upon which the whole structure rests. An annular foundation of brick work upon this supports the bases of the columns, ten in number, each 25 ft. high and 2½ in. thick. Upon these columns rests a heavy ring of structural material better shown in detail in Fig. 3, and to this mantel is riveted the shell of ¾-in. steel plate, 36 ft. in diameter at the bottom and 23 ft. 11 in. in diameter at the top. This shell is riveted up with the same class of workmanship as that used in the best steam boilers. Within this shell is the brick work about 4 ft. thick at the level of the mantel and maintaining nearly this thickness all the way to the top. Below the top of the mantel the brick work is thinner down to the tuyeres and then below the tuyeres thicker again, finally uniting with the furnace bottom, which consists of some 8 or 9 ft. of solid fire-brick work on the concrete foundation.

This structure is in broad outlines typical of the standard construction of to-day, but the variations of detail are almost as numerous as the individual furnaces. It is impossible to describe all these variations individually, but by dividing the furnace into zones we may deal in some detail with the conditions to be met and the approved forms of construction in each. The zones in which the furnace should be divided for this purpose are the hearth and bottom, the tuyere zone, the bosh, the shaft and the top.

### The Hearth and Bottom

The necessity of resistance to chemical action for the furnace as a whole has been briefly described above. This is particularly necessary in the hearth and bottom because these actions are the most intense in that region and because the consequences of failure of these structural parts are so disastrous.

The hearth of a furnace just before the cast time contains normally 60 to 80 and may readily contain 150 tons of molten iron and 20 to 40 tons of slag. The effect of pressure in intensifying chemical action has already been mentioned and in the hearth this condition is exaggerated by the fact that the pressure due to the depth of metal and of slag on top of it, is added to the pressure of the blast which, of course, is highest at the tuyeres. We may have, therefore, a depth of 7 or 8 ft. of metal with 2 or 3 ft. of slag laying over it, exerting a pressure of 3 lb. per square inch for each foot in depth of iron, and about 1 lb. for each foot in depth of cinder, so that we can easily have a liquid pressure of 25 or 30 lb. in the bottom of the furnace in addition to the 15 lb. of blast pressure in one properly working or perhaps 30 lb. in one working irregularly, so that the total pressure in the hearth of the furnace may easily approach 50 lb. per square inch.

If this be not firmly resisted and the least yielding takes place a crack will occur in the brick work and the metal instantly following this crack will approach the outer wall of the structure which supplies its physical strength, and if it succeeds in reaching this at some point not completely protected, the stream of liquid iron will quickly cut a hole through the iron or steel jacket around the brick work, and the stream of metal flowing through this hole will enlarge it with a rapidity which is almost beyond belief except by those unfortunates who have had experience with this action.

In one case which came under my personal experience the stream of iron cut through the hearth jacket a hole elliptical in shape and about 3 ft. long by 1 ft. high, with its long axis horizontal. Even if the hole be many times smaller than this the entire contents of the furnace are ejected through it under the action of their own weight, and the pressure of the blast in a few minutes, and this vast mass of molten material with the tremendous cutting power which flowing streams of such molten material have destroys anything metallic in its path in short order, and in very many cases has cut and seriously damaged the columns supporting the furnace structure. If this runaway body of metal strikes a wet place on the floor of the cast house or on the ground an explosion is almost certain to result which may be disastrous in its consequences. Furnaces have even been put out of blast by the results of such breakouts, and even worse cases are only too numerous in which men around the furnace have been injured or killed by such accidents.

For this reason the construction of the hearth and bottom of the furnace has received an enormous amount of consideration and experienced furnacemen are quite generally of the opinion that any reasonable amount of money spent in securing a construction immune from breakouts is well invested, a conclusion with which I thoroughly agree.

A construction which in general meets this object has finally been developed, and is illustrated in Fig. 3, which shows in vertical half section the lower part of the blast furnace of the Inland Steel Company at Indiana Harbor, Indiana.

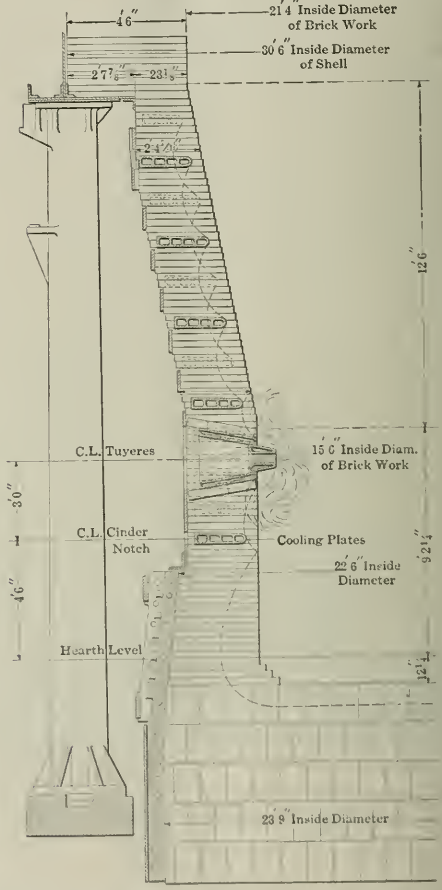

FIG. 3—HEARTH AND BOSH OF INLAND STEEL COMPANY'S "B" FURNACE

The metallic part of the construction consists of a series of steel staves with coils of cooling pipes cast in them, which extend from about 4½ ft. above the bottom level of the furnace to about 6 ft. below it. These are not fastened to each other, but are surrounded by an outside jacket. The lower part of this consists of a heavy rolled steel jacket riveted together with internal and external butt straps, no pains being spared to make the strongest joint possible, this jacket is separated from the staves by a small expansion space filled with yielding material.

The upper part of the staves is surrounded by a cast-steel jacket which also has water-cooling pipes cast in it. Its staves are fastened together by links shrunk onto the projecting lugs. They are of great thickness and, being made of steel castings, are enormously strong, but are further reinforced by rolled steel bands about 3 in. thick by 1 ft. in height around the top and bottom. The edges of the segments of this upper cast steel jacket are carefully planed to make a perfect joint, it having been found by experience that if there be an open joint in the jacket no matter how solidly the brick work may be built inside it, sooner or later the iron is likely to worm its way through the brick work and reach this crack. The instant the iron reaches it and begins to flow through it, the crack enlarges by the cutting power of the metal and soon a full-fledged breakout takes place which nothing can stop until the furnace is empty.

For this reason no pains or expense are spared to make hearth jackets not only strong enough to resist the expansion of the brick work and to prevent their rupture by this action, but also to make them of practically air-tight construction.

It was formerly considered by many furnacemen exceedingly dangerous to have internal water cooling below what is known as the iron line—that is, the height to which the iron may rise in the ordinary course of operation—this height being normally some 2 or 3 ft. below the center of the tuyeres, though in case of trouble the iron may rise up to the tuyeres. The reason for this objection to water-cooling is that a current of iron flowing with considerable velocity will cut a water pipe or other cooling apparatus with the water flowing through it, since it is impossible for the water to remove the heat as fast as the stream of iron supplies it. When a cooling member is cut in this way explosions are almost certain to occur, and these are more disastrous the more confined the location in which they take place. Many frightful accidents have occurred through the cutting of water-cooled parts by molten iron.

When the joints in the outside jacket are absolutely tight such a flow of metal cannot start, and as it is only a flow which possesses this tremendous cutting power, the cooling pipes are not endangered by this action when there are no crevices through which the iron can flow past them. By the combination, therefore, of the tight jacket, and the water-cooling staves inside it, the danger of breakouts which formerly was almost the worst dread of the furnaceman's life, have been reduced to a minimum, almost to a negligible quantity.

It will be noticed in Fig. 3 that there is a thickness of three feet of brick at the top of the hearth jacket, and that this increases toward the bottom. This is for the reason that the high velocity at which the blast is injected through the tuyeres gives it a mushrooming effect indicated in Fig. 3, which throws it back against the wall around the tuyeres and tends to cause severe cutting, augmented by the heat and chemical activity of the molten iron and slag. These jointly tend to cut away the hearth as shown in dotted lines, but by having an ample thickness of brick and having the line of water-cooling of a much larger diameter than that of the nose of the tuyeres, the water-cooled surfaces have a better chance to overcome this combined action, so that furnaces built in this way cut back to a certain distance and then stop, whereas if the outside diameter of the hearth were made smaller in relation to the tuyere diameter the probabilities are that it would eventually give way under the joint attacks of these three influences.

It was formerly thought that every furnace had to have one or two breakouts when it started to working properly soon after it was blown in, and in the days when furnaces were small and the quantity of iron in them at one time was only a few tons, this, while a bad condition, was endurable, but, as furnaces and their outputs have grown and the amount of metal released by a breakout has increased, it has become increasingly necessary to solve this problem almost irrespective of the cost of the construction. The evolution of the general type described is the result of necessity.

### THE DITCH AROUND THE HEARTH JACKET

There is ordinarily a ditch around the outside of the hearth jacket extending from just above the base of the columns, which are bricked in solid, up to about a foot above the hearth level, and practice in regard to this ditch has varied greatly. It is customary to use this to carry off the waste water from the tuyeres, coolers, etc., and formerly these ditches were kept full of water to their tops, with the idea that this furnished effective cooling of the hearth jacket and tended to prevent breakouts. But in order to keep the ditch full of water its outlet must be dammed, and when this was done if a breakout did occur the molten iron filled up the ditch to the level of this dam, part way or even all the way around the furnace, and when cold had locked itself between the columns and the hearth jacket, whence it was almost impossible of removal.

At one time the practice prevailed of filling the ditch to the top with large lumps of limestone piled in as loosely as possible, then if a breakout occurred the decomposition of the limestone by the heat and the subsequent slacking of the lime tended to crack apart the mass of iron, which, of course, was much reduced in quantity and solidity by the presence of the lumps themselves. This practice is an improvement, but the practice of carrying the ditch full of water is itself going out of vogue to some extent, and personally I would never have the water in the ditch more than a couple of inches deep if it could be avoided. This enables the ditch to be kept open to the bottom, and if a breakout occurs the molten iron will run out the outlet and leave the ditch comparatively free. Moreover, more effective cooling may be obtained by the spray from a small circle pipe causing a thin film of water to trickle down over the hearth jacket than can be obtained with a large body of standing water. This has often been established and is another illustration of the principle that rapid circulation has as much to do with heat conduction as the amount of surface and conductivity of the material involved.

Allowing the outlet from the ditch to carry off the iron in case of a breakout has some disadvantages because the iron itself will run along the bottom of the ditch underneath the water for long distances, even in quite small quantities. I have known it to go 60 or 70 ft. and plug up the screen over the waste opening into the sewer so as to create a fearful nuisance.

To meet this situation two expedients are available, one of which is extremely simple and should always in my judgment be used. This consists in having an auxiliary outlet from the ditch normally kept closed and designed to discharge at some point sufficiently removed from the furnace so that any iron carried off by it may do as little harm as possible. This ditch may be closed either by a hand-operated gate or by a thin lead plate. The latter will cut off the flow of water effectively, but will melt in case iron strikes it and open up the emergency outlet. This should preferably be placed lower than the main outlet so as to drain the iron completely away from the latter. The use of this expedience once saved a shutdown of many hours at a plant formerly under my management.

The other expedient is somewhat more expensive. It consists in building a large chamber or cistern in the bottom of the outlet ditch, which is covered over by the cast house floor plates under ordinary conditions, and stands full of water all the time, the wastewater current simply passing across its top, but if a breakout occurs the iron will run into this cisterm and has to fill it up before it can go on through and make its way into the outlet sewer, the plugging of which constitutes a calamity of no mean order.

It is frequently customary to have the ditch around the furnace interrupted by a solid structure of brick on which the iron-trough beneath the tapping hole is supported, but I do not like this construction, as the heat is drawn through the hearth jacket by the poulticing action of this brick pier and the circulation of water is cut off by it. Moreover, in case of a breakout the presence of this dam in the ditch prevents the iron from draining away in that direction and may result in permanently filling the ditch with a mass of iron at that point.

By riveting a pocket a little larger than the outside of the iron trough air-tight on to the front of the hearth jacket the trough can be set down into this and a joint made between the two with cement, the water can then rise practically to the bottom of the iron trough without any danger of getting into it, and yet have an absolutely free circulation around the base of the hearth jacket at this point, which probably needs it more than any other.

### The Tuyere Zone

This is the zone between the top of the hearth jacket and the bottom of the sloping bosh. Various styles of construction have been adopted for this, as for all the other regions of the furnace. One of these which had much vogue at one time was the use of a heavy cast-iron or even cast-steel tuyere jacket with cooling pipes cast in it, and with openings cast through it of the size required by the coolers, no internal cooling by cooling plates being used.

This construction and all others which depend on external cooling in this zone are in my opinion faulty for the reason that the tuyeres must project a considerable distance into the furnace. If they did not, what I have called above the mushrooming effect would rapidly destroy all the parts adjacent to them; therefore, we have first the hollow-walled cooler as a sort of second line of defense which projects into the face of the brick work. Then fitted into this and projecting about a foot beyond it we have the tuyere itself, its nose being some 3½ or 4 ft from the exterior of the brick work, which is literally on the firing line.

The mushrooming effect of the blast, if this zone were without any but exterior cooling, would soon eat away two or three feet of the face of the brick work, which would leave the heavy coolers carrying the tuyere without adequate support. This in turn would allow them to drop down so that instead of directing the blast in horizontally, as they should, it would be blown downwardly into the bath.

To overcome this and to protect the zone around and between the coolers from this intense mushrooming effect, cooling plates are used as shown in Fig. 3. These are hollow plates of copper, or copper with one or two per cent. of tin to make it cast more readily, with a taper in the vertical plane, as shown, and also in the horizontal plane. These are supplied with water from the water-cooling system and a constant circulation kept up through them the same as in the tuyeres.

They are built into the brick work, but on account of the taper above mentioned can be withdrawn by means of lugs provided in their rear or outer surfaces for that purpose. These have a great cooling surface and corresponding protective power for the brick work around them. They increase the resistance of the brick against the action of the fire, and the brick to a great extent protects them from the direct attacks of the latter, although frequently they are directly exposed to it, as are the tuyeres, but able to resist because of the activity of the water-cooling, in exactly the same way that the fire box of a locomotive is able to withstand the intense combustion of the fire within it because the thin plates which constitute its inner surface are so completely cooled by the water around them.

It will be seen that these cooling plates with their ability to withstand the direct action of the fire, protect the fire-brick work underneath and around the coolers from the attacks of the iron, the slag and the mushrooming effect of the blast, and so enable these to maintain their correct position throughout the campaign.

In order to supply the element of strength against the internal pressure of the furnace two constructions are possible. Either bands can be passed around the furnace just above and just below the cooler openings, leaving the space between these bands unprotected, or the bands may be connected by vertical buckstays which protect the intermediate space. The construction which I like best of all, however, is to make a solid jacket of steel plate, as shown in Fig. 3, with the flange at the base resting on the top of the hearth jacket, with holes cut through it at the points where the cooler openings and the cooling plates come. This supplies the means of holding all the brick work to its place, which is necessary, for, in the absence of such protection, it is surprising how small a mass of unbound brick work will detach itself from the rest and work out of the furnace under the action of expansion, pressure, etc.

### The Bosh

This divergent cone which begins at the top of the tuyere zone has received attention at the hand of a vast army of engineers and furnacemen, and many solutions of the problem of a suitable construction have been attempted. The divergent shape of this portion of the structure and its relative lack of solid foundation upon which to build a patch if it fails, combined with the scouring action of the blast traveling up it, and of the semi-reduced iron and scouring slag travelling down it, have made the problem of maintenance of this part of the furnace a difficult one.

One of the most commonly used constructions is that shown by the upper portion of Fig. 3. It consists of several rows, in this case eight, of cooling plates, those in one horizontal row alternating in vertical location with those in the rows above and below it. In other words, the plates in each of the eight horizontal row are not vertically above one another, but are staggered for reasons of mechanical strength, because the plates are very much weaker against compression stresses than the brick work, and if they were all in one row might be crushed by the expansion of the boshwalls due to the heat. By having them in alternating rows larger masses of brick work intervene between them, making a sort of series of arches which do not readily crush. Moreover, if all these cooling plates were arranged in vertical rows, the brick work between these being relatively without protection would be scoured out by the erosive actions I have mentioned.

By staggering the plates vertically the space between a pair in one row is protected to a great extent by the plate in the other rows above and below that space. This construction is shown in Fig. 4. Just above the bustle pipe portions of two rows of cooling plates and their vertical staggering may be quite clearly seen.

The cooling plates must be protected from the weight of the brickwork above them and this is done by one of two methods. Either a flat arch is turned in the brickwork above them or a cast-iron box is built into the brickwork which projects in from the outer wall about one-half or two-thirds the length of the cooling plate, which is inserted through and protected by this box. Both methods are good but the brick arch is much cheaper and just as good for all practical purposes, so is to be preferred.

Circumferential strength is supplied by very heavy bands of steel running around the bosh between the rows of plates. This makes a good strong substantial construction, but in addition to being very expensive on account of the great quantity of copper castings required, it is liable to one serious fault. This is that the erosional influences I have mentioned cut out the brick work between the plates and leave the noses of the latter sticking out into the furnace almost like a flight of steps. I have tried to illustrate this action by the dotted lines in Fig. 3 and can state most emphatically that the conditions shown by this sketch represent only a fraction of the erosion that I have seen in actual practice after a campaign of only a year or two.

When the action has proceeded to the extent indicated or further, the shelves formed by the projecting noses of the cooling plates make ideal lodging places for half molten slag and such materials as it cements together, and such a mass builds up on the noses of the plates at times with considerable rapidity. Then a change in the condition of the furnace comes about or the accumulations are no longer able to maintain themselves on the narrow footing offered by the cooling plates, but in either event the whole mass sloughs off into the hearth and having no time to be treated by the heating and reducing action of the ascending gas is precipitated into the hearth in a half raw condition with resulting ruin to the iron and slag already formed therein, and the partial chilling of the furnace, perhaps to a serious extent.

It is these steps and the consequent irregularity of the work of the furnace at times which has led some furnacemen to abandon this type of construction for one whose wearing surface should be smoother and more regular. This result has been sought in some cases by building up a water-cooled bosh jacket of cast-iron segments as shown in Fig. 5. These segments as shown are strongly bolted together to supply the necessary strength to resist the pressure, and then receive a thin lining of brick, its thickness depending upon the opinion of the furnacemen as to what is necessary, but commonly from nine to eighteen inches. This is an expensive construction and requires careful machining throughout, because if the least crack exists the gas will blow out through it with destructive effect and on account of the crack being small it is almost impossible to get anything in the nature of a clay stop to stay in it.

A third type of construction consists of a bosh jacket made entirely of steel plates and cooled solely by external sprays. This can be made an absolutely airtight job of boiler work, thus eliminating any possibility of gas leakage such as I have described, while the cooling by means of a continual film of water on its exterior surface produced by sprays is one of the most efficient forms which can be obtained in any way whatever, a much greater surface being exposed to the

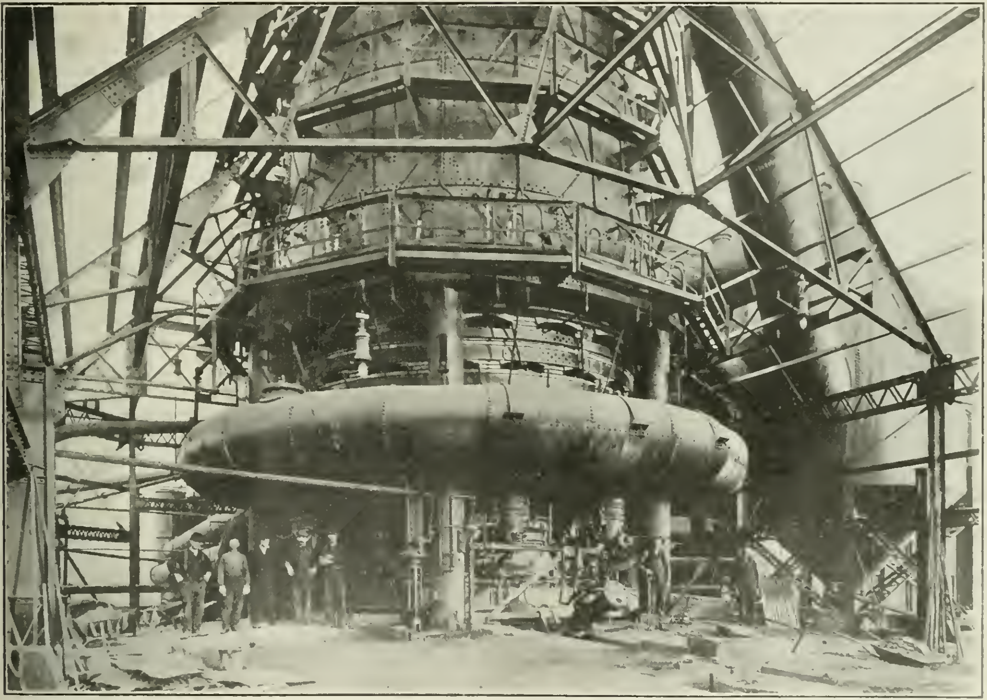

FIG. 4—LOWER PORTION OF FURNACE SHOWN IN FIG. 1

cooling action of the water than in the case of the cast-iron built-up jacket.

One feature of a jacket of this kind must receive the most careful attention. It must be as near absolutely smooth as it can be made by good workmanship. The rivets must be countersunk on the outside and driven down absolutely flush so that a film of water will travel over their heads without any interruption, and in general everything must be done to remove even the slightest obstruction from the path of the water film, because this film travels down the surface with a considerable velocity and even a minor obstruction will throw it off leaving a dry spot below the obstruction. This dry spot becomes hotter than the rest of the jacket and causes contraction strains and in time cracks result, while if it be a large one the lining on the inside of the jacket will melt off and the jacket itself will then be exposed to the assault of the streams of iron and slag running down inside it, which will soon cut a hole through it. Such holes are almost impossible to stop without a long shutdown on the furnace to enable a patch to be put on, and as this can only be done with patch bolts it is never anywhere near as good as the original jacket.

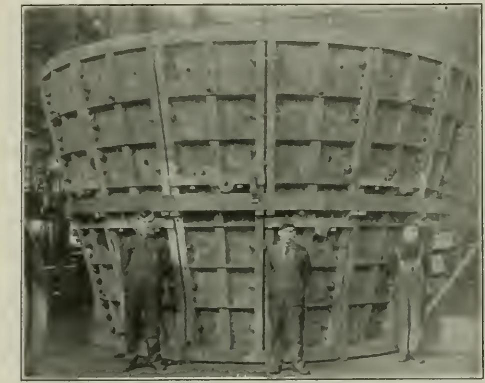

FIG. 5—SEGMENTAL BOSH JACKET BUILT BY BIRDSBORO FOUNDRY & MACHINE COMPANY

This is one of the places where an ounce of prevention is worth a ton of cure, and the only proper course is to make it impossible for a dry spot to form on one of these jackets.

Fig. 6 shows a furnace reconstructed according to the plans of the writer with a jacket of this type in which absolute smoothness was obtained by welding it up with an oxy-acetelyne burner, then chiselling off the roughness at the joints and grinding it down smooth, an operation which took little time and cost a relatively small amount, something like a couple of hundred dollars above the cost of boiler work.

This jacket was flanged out at top and bottom to avoid the necessity of riveting angles on it to make connections to the mantel plate above and to the trough at its base. By flanging the metal out bodily these riveted joints are avoided.

Water is sprayed into the top of this jacket by a circular spray pipe divided into eight sections, each of these being connected to the water supply separately, and each of them also being in duplicate, only one being used at a time. If one becomes obstructed or fails the other can instantly be put on. This feature, as a matter of fact, is used only when it is occasionally necessary to clean out one of the sections, but it is a convenience at that time and contributes to safety at all times and is well worth the trifling expense.

Some care should be taken to supply the water to these sprays under a very moderate head and make the holes in the spray pipes fairly large. They are then much less likely to become obstructed by small threads of pump packing and like and can be made to deliver the water exactly at the top line of the jacket with a minimum of spattering, the water thrown on to the jacket flows down it in a smooth film and the spatter is caught by the annular funnel shown about half way down the jacket, which is not riveted to the latter but comes in contact with it through a serrated edge at the bottom of the funnel. This serrated edge gives sufficient flow at every point around the circumference which would not be the case if the bottom edge of the funnel were straight as the contact would be close enough in that case to cut off all flow in places.

By having the funnel hung from above by independent hangers it is possible to adjust the location of its bottom edge in relation to the jacket with small wedges to regulate the flow and get it uniform around the furnace, which could not so readily be done if the two were rigidly connected. Moreover when the funnel is supported from the jacket this involves rivets in the jacket for the funnel brackets and below these rivets it is almost impossible to avoid having a dry spot as above described.

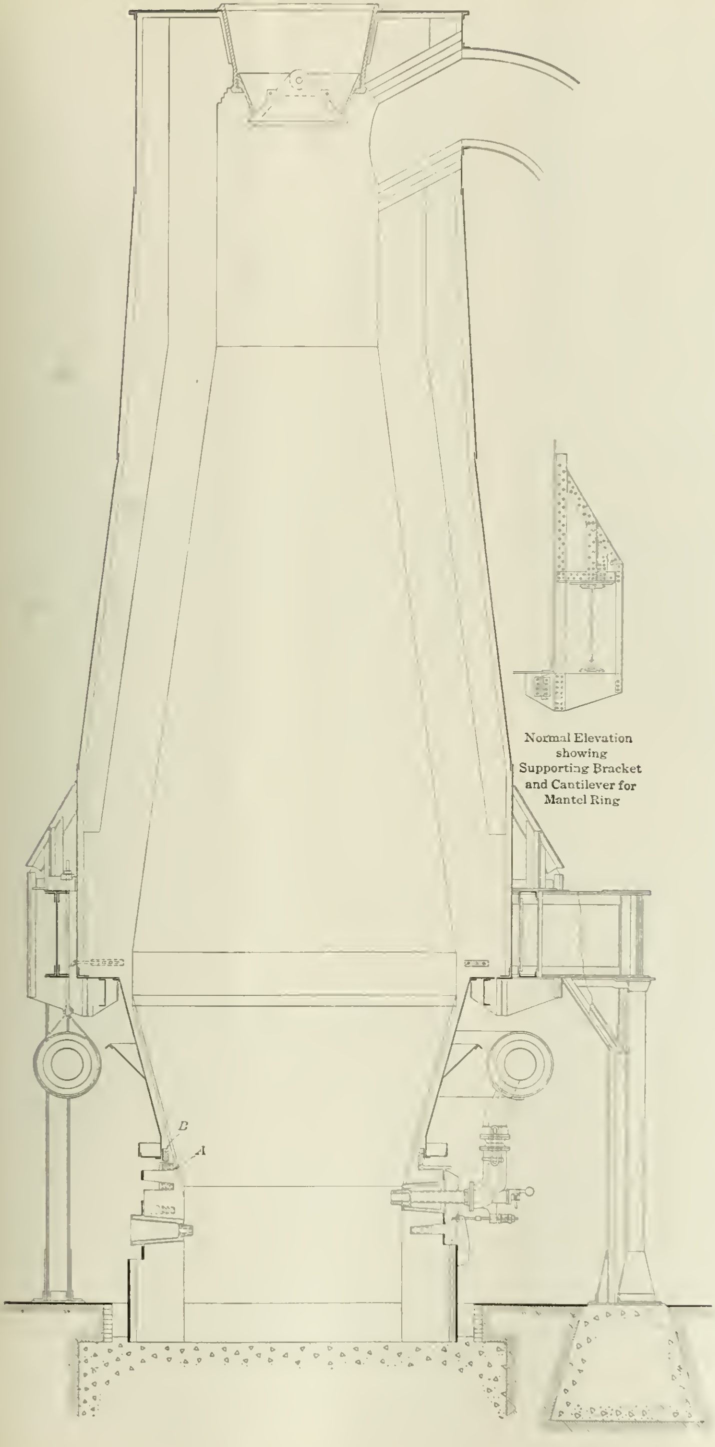
This jacket was so extremely smooth and worked so admirably in service that the intermediate funnel could probably have been dispensed with entirely by widening out the bottom trough a little more and perhaps putting some flanged extensions around its upper edge to catch spatter.

The trough as shown projects out beyond the base of the funnel, but should have been made three or four inches wider than it is because some of the drops from the bottom edge of the funnel are deflected from the vertical line by capillary attraction and fall outside the line of the trough which cause disagreeable spattering down below.

When using a construction of this type it is not only possible but far preferable to use a very thin brick lining in it, because the brick being cooled only from the outside will rapidly wear down to that thickness at which as much heat is carried away from their bases as the currents of molten material and gas supply to their front surfaces. This is only a few inches and if three feet of brick were to be built inside such a bosh jacket in the course of a few months it would all be gone down to a few inches, exactly the same as if it had started at one foot or even nine inches in thickness. Consequently if the furnace were the correct shape to begin with it obviously could not be so with three feet of brick scoured off the bosh all around, therefore the thing to do is to put in only as much brick in the first place as the furnace may be expected to leave there after it has settled down to regular work.

In coke furnaces using a bosh of this type I have several times used only nine inches of brick with very satisfactory results, and in the furnace shown by Fig. 6 which was to use charcoal and therefore much easier on the lining than a coke furnace, I used only four and one-half-inch bricks made up specially as circle bricks to fit the curvature of the bosh. This furnace was blown out on account of commercial conditions after a campaign of about a year and a half, and two inches of the original brick was still left. The judgment of the furnacemen was that it was as good as new.

A point about this construction which must not be overlooked is that the lining in this portion of the furnace is practically self-renewing. If the brick were



Normal Elevation showing Supporting Bracket and Cantilever for Mantel Ring

FIG. 6—CHARCOAL FURNACE, SHOWING STEEL BAR JACKET CONSTRUCTION

all scoured off the jacket clean by bad slag or bad work of the furnace, and the water-cooling were maintained, within a few hours the furnace would have built back itself a lining of slag, carbon dust, etc., just as resistant for its purposes, if not more so, than the fire-brick initially used.

This condition arises from the fact that this portion of the furnace converges toward the bottom, and that any material chilled on it tends to stay because of its conical shape. This is a feature of much importance which does not exist in any other portion of the furnace.

Owing to the small quantity of brick in the lining of the bosh in this construction it is without much compressive strength and differs in that respect from the cooling plate construction of Fig. 3 in which a considerable portion of the weight of the furnace structure is carried on the hearth and bosh walls when the latter are heated up by expansion. With the steel-plate bosh construction this must not be allowed to happen as the thin brick lining would quickly crush and the steel jacket buckle with disastrous consequences under compressive stress. It is necessary, therefore, to provide a sort of expansion joint in which the expansion due to the heating of the brick can be taken up without objectionable consequences. That is accomplished in the present construction by making the lower portion of the bosh jacket proper, cylindrical and putting inside it a set of cast iron water-cooled housings or blocks through low opening in which project cooling-plates as shown at A. These cast-iron housings and the cooling-plates are supported on the heavy brick structure around the tuyeres which extends up from the bottom. The bosh jacket and its lining on the other hand are practically suspended from the mantle.

When expansion takes place the cylindrical portion of the bosh jacket slides down over the water-cooled housings, and if the lining is cracked or broken by this action, the crack is at once sealed by cinder running down over the surface and chilling against the housing and the bosh jacket.

In order to avoid the necessity of lugs and fastenings on the housings they are held together by the band B around their tops, this band being protected from burning by the cold bosh jacket just outside it and the water-cooling within the housing.

The water pipes for the cooling blocks A were brought out at the bottom so that the maximum of expansion could take place without shearing off these pipes, which has been known to happen in a construction of this kind where this provision was not made for it. Even in this case it would have been better if the space between the bottom of the trough and the top of the solid brick wall had been made three or four inches higher.

The water-cooled *housing* and the cooling plates projecting through them perform a double function, they protect the *tuyeres* and coolers below them for the scouring action of the streams of iron and cinder and prevent the spaces between the coolers from being scoured out and so weakening the tuyere zone. Secondly they form a water-cooled shelf at the foot of the bosh slope which supports the lining of the latter and forms a ledge on which a new lining can start to form in case the old one is scoured off by irregular furnace work.

Both these functions are of great importance and some portion of the construction to perform them must be supplied if this type of bosh is to give the long and useful service of which it is capable. When properly designed there is no doubt that this type of bosh construction will give absolutely satisfactory results in furnace operation on account of the perfectly smooth slope of its working surface and the complete absence of steps on shelves, at a cost of construction which is literally only a small fraction of that of the cooling plate or water-cooled stave construction.

*(To be concluded)*

## Colorimetric Estimation of Gold in Cyanide Solutions

It sometimes happens that conditions of precipitation are disturbed temporarily, and frequent determinations of gold in barren solution are desirable in order to control the precipitation process. Time is not available for the ordinary assay, and a rapid method is required which can be performed by the foreman or shiftman in charge of the work. In discussing a paper on the metallurgy of the Homestake ore, presented to the Institution of Mining and Metallurgy by Messrs. A. J. Clark and W. J. Sharwood,[1] Mr. Charles B. Brodigan recorded such a method devised by Mr. Dowsett, reduction officer at the Brakpan mines, South Africa.

With slight modifications, the method of Mr. Dowsett has since been adopted at the Homestake mill for testing barren solution, and we are advised that by its use the mill foremen are able to detect with surprising accuracy variations of 1 cent per ton, in solutions carrying from 1 up to about 15 cents per ton. Seven minutes is sufficient for a test, and the method is extremely useful when conditions of precipitation are unsettled and frequent determinations necessary. No standards are used, the grade of solution being estimated by the depth of color obtained. The color for a 1 or 2-cent solution is very faint, but is readily detected after a little practice. For successful work it is important that the cyanide solution used be of the highest possible strength.

In his original contribution Mr. Brodigan states: "If gold is present to the extent of 0.02 dwt. (2 cents) per ton of the original cyanide solution a very slight coloration will be perceived in the liquid; 0.03 shows a slight yellow; 0.04 slight pinkish-yellow; 0.06 strong pink; 0.08 the purple of Cassius."

### The Method

Details of the method as employed at the Homestake are as follows:

*Reagents required.* Zinc dust, sifted through 200-mesh sieve.

Hydrochloric acid, concentrated C. P.

Nitric acid, C. P., 1 acid; 2 water, in dropping bottle.

Lead nitrate, saturated solution, in dropping bottle.

Sodium cyanide, saturated solution.

Tin chloride, about 12.5 per cent crystals + 10 per cent concentrated hydrochloric acid.

Place about 500 cc of the sample to be tested in a light-colored, sample bottle having a very slight shoulder; a quart beer bottle is about the right size. Add a measured quantity, 10 to 15 cc, of saturated sodium cyanide solution; two or three drops of saturated lead nitrate solution; and from 1 to 2 grams of zinc dust. One gram of the dust usually will be found sufficient. Stopper the bottle with the thumb and shake violently for at least two minutes, or until the precipitate is completely coagulated and will settle rapidly.

Invert the bottle over a casserole and allow the precipitate to settle. Remove the bottle and decant the clear solution from the casserole. Add hydrochloric acid to the precipitate, drop by drop, until the reaction ceases, and then add a few drops in excess. Add three to five drops dilute nitric acid, heat and evaporate to a volume of 1 or 2 cc. Transfer the solution to a small (½-in.) test tube, cool, and add about 1 cc tin chloride. A purple color indicates gold.

With low-grade solutions the tube should be allowed to stand a minute or two to bring out the full color. Faint colors may be seen better by looking down the tube. Some variations in the amount of cyanide, zinc dust or lead nitrate may be necessary with different solutions. The lead should be kept down as far as possible, using the minimum that will give a precipitate that settles rapidly, as this will require a minimum of nitric acid. Too much nitric acid may interfere with the production of the final color. Mercury also gives a dark coloration, and somewhat affects the color given by gold.

**The extension of flotation** to the treatment of disseminated copper ore is indicated in the report that the Nevada Consolidated Copper Co. will install a flotation unit for experimental purposes.

**Progress at the new mill** of the Alaska Gold Mines Co. is said to be satisfactory. The steel for the coarse crushing unit is practically erected, and the roll and concentrating sections are under way. Concrete for foundations in the roll plant has been poured at the rate of about 300 yd. per day.

**The smelter smoke nuisance** is not confined to the western states. Residents of Staten Island, N. Y., have succeeded in having indictments returned against a number of New Jersey smelting and refining companies, charging them with maintaining a nuisance detrimental to public health and property. The court and counsel for the defendant companies have indicated their desire to effect an amicable settlement.

**Refining of platinum** is performed in the San Francisco branch of the Bureau of Mines by boiling the metal, about 75 grams at a time, in a cupel heated by an oxy-acetylene flame. The metal thus refined is softer and more pliable than before the treatment.

# Three-Metal Bronzes

BY ALLMAND M. BLOW

A great many of the commercial bronzes and the trade-named bronzes, which are really brasses, contain added metals besides copper and tin, either for the beneficial properties derived from such additions, or because impurities are present which do not seriously affect the alloy under working conditions. The last is not true for impurities such as sulphur and oxygen; whereas iron, frequently present in small quantities in spelter, is a beneficial impurity, and special means are often taken to alloy it perfectly with bronze. Among the principal metals added to bronze are lead, zinc, phosphorus, manganese and aluminium, and as such they comprise a group of special bronzes or three-metal systems, in distinction to the regular copper-tin alloy. In addition, a number of commercial alloys are sold as bronze, when they are really of a zinc base. In general, the higher price demanded for bronze and the excess price of tin over zinc to the manufacturer, is the cause of this. Before going into the effect of other metals on bronze a brief outline of the true copper-tin alloys will suffice.

## Copper-Tin Alloys

Fig. 1 is the familiar copper-tin temperature-composition diagram as originally worked out by Heycock and Neville. Other investigators claim a few slight variations from this curve, but for the most part it is generally accepted. The portion *B C c d* is the disputed area, wherein additional changes are claimed to take place.

At any temperature and composition above the line *A B C D E F* copper and tin form a homogeneous liquid. A decrease of temperature to this line (liquidus) immediately starts the freezing out of certain constituents of that liquid, depending on the composition. The line *A b c d g h i j F* (solidus) likewise indicates the completion of the solidification. An alloy of a certain composition, at a temperature above the liquidus, will, on cooling to room temperature, go through certain reactions at the horizontal and curved lines, and contain such constituents as are included in the vertical lines.

The series contains two solid solutions, alpha and beta, and three compounds CuSn, $Cu_3Sn$ and $Cu_4Sn$. The former are true solid solutions of tin in copper as they are homogeneous in structure throughout. The eutectic, or alloy of lowest freezing point, is at 1 per cent copper. A change in the solid state, or eutectoid point, occurs at about 25 per cent tin. The alloys containing high copper are of the greatest importance and as the percentage of tin increases the alloy becomes brittle and therefore of less use. However, at about 80 per cent tin the alloy is practical but contains too much tin to compete profitably with other alloys of equal properties. The usual alloy does not contain more than 25 per cent tin and up to this composition there are two general classes, *i.e.*, tin from 0 per cent to 12 per cent, sheet bronze and gunmetal; and tin from 10 per cent to 25 per cent, bell-metal. Considering the diagram from left to right, solid solution alpha is obtained up to 10 per cent tin. From this point to 25 per cent tin an alloy on cooling will freeze out alpha when reaching the line *A B*. The liquid remaining will follow this line down to *B* where at 795 deg. C. there will be alpha of 10 per cent tin and the liquid of 25 per cent tin. A reaction then occurs whereby solid solution alpha + liquid *B* — solid solution beta. Beta will form as long as both of these are present and the alloy will finally solidify completely when one or the other is used up. Decreasing amounts of tin from 25 per cent will cause the liquid to be used up first, leaving more alpha in proportion to the decrease toward 10 per cent. In any case, the alloy is solid at 795 deg. C., and then further lowering of the temperature caused the beta formed (22 per cent tin) to pass down the line *c e*, which is accompanied by the formation of a little more alpha until the eutectoid point at 500 deg. C. is reached. Here a further change takes place by the breaking down of beta into a mechanical mixture of alpha and $Cu_4Sn$, or the eutectoid. On the other side of this point, beta will throw down one or both of two compounds instead of alpha. Above 32 per cent tin, $Cu_3Sn$ will form first from the beta and at 580 deg. C. a reaction produces, $Cu_4Sn$. From 25 per cent up to 32 per cent tin the latter will form first, and as before, at 500 deg. C. the eutectoid of alpha and $Cu_4Sn$ will cease the changes.

The rate of freezing and cooling will affect these compounds and solutions to a great extent, both in their composition and structure. Alpha, according to the diagram contains nominally 10 per cent tin in solid solution. Long annealing will increase this to 12 per cent without the eutectoid appearing, whereas in the practice of casting, the eutectoid may be seen when only 6 per cent tin is present. The eutectoid contains $Cu_4Sn$ which is hard and brittle and is therefore not generally desirable. Gunmetal, according to the previous classification is then all alpha. For a combination of strength, elasticity, toughness and ability to withstand shock, alpha is the most desirable. Other metals increase these properties; but a true bronze containing 9 per cent tin has the following values:

| | |
|---|---|
| Tensile strength | 32,000 lb. per sq. in. |
| Elastic limit | 13,000 " " " " |
| Elongation in 4 inches | 14 per cent. |

Since no transformation points are passed in the annealing of alpha bronzes, they are practically uninfluenced by heat treatment. But as the tin content is increased more of the eutectoid is present and the alloy comes into the class of bell-metals, which are hard or soft, and will have different tones depending on the amount of $Cu_4Sn$ content of the eutectoid. These alloys above 12 per cent tin are very susceptible to heat treatment. By quenching from above 500 deg. C. (formation of the eutectoid) the eutectoid is partially prevented from forming and the alloy is more malleable by containing beta.

Tin up to 32 per cent produces an increasing amount of $Cu_4Sn$, until just at 31.8 per cent pure $Cu_4Sn$ is obtained. This alloy is given the name of Speculum metal because of the high polish it will take, thus adapting it to minor uses. It is very brittle. A mixture of $Cu_4Sn$ and Cu Sn is obtained in the range 31.8 to 38% tin.

The solid solution beta breaks up into the eutectoid when slowly cooled so that equilibrium is established. However, in this range of composition the alloys are much influenced by heat treatment and quenching. The microstructure of an alloy quenched from within this range shows that some of the beta is retained in the final metal. By treating in this way, the most beta is retained in alloys from 22 per cent to 25 per cent tin, and consequently the final state will consist of beta, alpha and the eutectoid in varying amounts. Beta is desirable to increase the tensile strength and for that property only it is more suitable than alpha. An alloy containing 22 per cent tin, treated so as to get the most beta, will have a tensile strength of about 40,000 lb. per sq. in. The other values are low. Alpha will increase the ductility at the expense of tensile strength, hence a balance must be obtained between the two.

Above 32 per cent tin brings the series into the range of $Cu_3Sn$ and CuSn, alloys containing which have little strength and seldom enter into the three-metal bronzes. At 80 per cent tin the useful properties are somewhat regained, rising from around 2000 lb. tensile strength in the middle of the series, to about 7000 lb., when the strength again decreases.*

### The Effect of Lead on Bronze

In most cases the addition of one metal to another gives a lower mutual freezing point, hence it follows that lead should have a decreasing effect on the temperature changes of the copper-tin diagram. This is found to be the case; and because of the soft nature of the lead and its much lower freezing point than that of a bronze of 10 per cent tin, the resulting alloy is softer, and, on account of these properties the name of "plastic bronze" is applied to this type. By discussing the equilibrium diagrams first, a clearer understanding of the physical properties may be obtained when the lead varies from maximum to minimum.

Fig. 2 shows the temperature-composition diagram of copper and lead. These two metals belong to the class of alloys that are incompletely soluble in each other in the liquid state and completely insoluble in the solid state. The curve given is generally accepted as correct by the many investigators of this alloy. An eutectic point is at practically pure lead (99.94 per cent) at 326 deg. C. Within the dotted half-circle there are two liquids corresponding to 10 per cent and 65 per cent copper; without it, there is a single homogeneous liquid. A copper-rich alloy will freeze out copper to start with when the temperature is lowered so as to strike the line *Cu G*. The liquid is robbed of its copper until at 950 deg. C. it contains 65 per cent at the point *G*. Then further freezing out of copper causes the formation of the second liquid containing only 10 per cent, and the temperature remains constant until no more of the first liquid remains. One liquid is formed at the expense of the other and copper is precipitated. When the reaction has continued to the point *H* then, and only then, will the temperature fall by freezing out more copper from the 10 per cent liquid, the final solidification being at 326 deg. C.

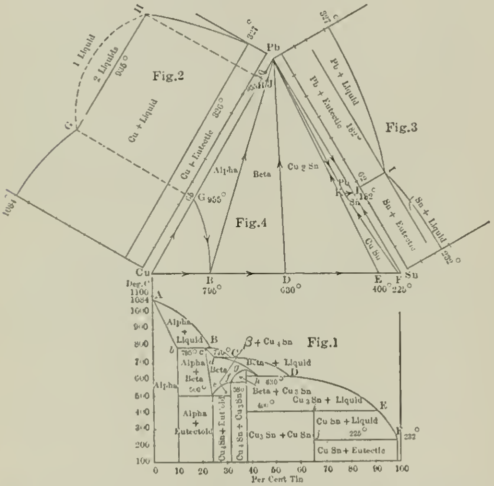

FIG. 1, 2, 3 AND 4—TEMPERATURE-COMPOSITION DIAGRAMS FOR COPPER-TIN, COPPER-LEAD, LEAD-TIN AND TERNARY

Lead and tin (Fig. 3) form a very simple curve with an eutectic point at 62 per cent tin and 182 deg. C. On either side of this point, as the case may be, lead or tin will freeze out first until the liquid is enriched to the eutectic composition; then the alloy will all go solid by the precipitation of this mechanical mixture of lead and tin, the eutectic. Under favorable conditions of cooling, a small percentage of lead (say 3 per cent) may be held in solid solution by the tin; and likewise for tin in lead.

By combining these three diagrams, Fig. 4, the ternary is obtained in which temperature is normal to the plane of the paper and the lines within the triangle represent projections to the horizontal of the intersections of the surfaces of the solid figure. Since each corner of the triangle represents 100 per cent of one of the metals, a surface connecting adjacent sides at this corner and projected on to the horizontal as an enclosed area, will include the first substance to freeze out when all three metals are present, should the composition of the alloy happen to lie within this enclosed area. Thus the area *Cu GB* shows that with copper and tin, alpha forms first; with copper and lead, copper is the first precipitant; but instead of having the two the excess copper produces more alpha, so the result is alpha alone in this area. Beyond the solubility of tin in copper to form alpha, other compounds are introduced represented by other areas, and the intersections mark the change from one to another. The arrows indicate the slope of the projected surface intersections.

A few of the internal change points of this ternary diagram, as to temperature and composition, have been determined accurately by early investigators, notably the direction and slope of the line *G B;* but as to the other parts of the figure there seems to be a lack of authoritative information. Consequently this figure is presented in the way of predicting the results we hope to obtain later, and, while the lines within the diagram will not, with our present knowledge, indicate accurately the limits in composition of the constituents, they will serve to enclose an area in which certain compounds and solutions exist.

Thirty per cent of lead in bronze is about the practical limit. Hence the lower left corner of the ternary is the most important. In the area *Cu GB*, alpha will freeze first. The line *G B* shows that as the temperature falls and this area is intersected, alpha is thrown out and the liquid follows the surface down on a line through the corner, then the saturation point (along *G B*) of the first liquid (originally 65 per cent copper) is reached sooner and at a lower temperature with increasing amounts of tin. This fact is to be noted later in connection with segregation, but since the copper-rich liquid still freezes out alpha to form more of the second liquid *H* (which gives alpha also), there is no interference with the formation of alpha, so it is likewise the first solid to form in the entire area, *Cu Pb B*. The line *H J* is similar to *G B*, marking the beginning of freezing of alpha from the lead-rich liquid. Final freezing takes place at 326 deg. C. when the lead separates out. The alpha formed by the above reactions follows the changes as described before. First will occur the reaction to form beta, then at 500 deg. C. it will give place to alpha and the eutectoid. The line *B Pb* represents this beta-forming reaction.

When there is sufficient tin in the alloy this line will be met on cooling and the liquid will follow it in the direction of the arrow, forming beta. Of course, the composition determines whether the alloy will all go solid before this line is reached; but as the tin increases above 10 per cent the conditions are more favorable and then the beta reaction continues along *Pb B* until no more liquid remains. In the area *G H J B*, at an elevated temperature, are the two liquids:

---

*The strength values given throughout this paper cannot be used for rigid comparison even with alloys of similar composition. Chilled and cast test bars of the same metal, and pieces of the same bar will often give varying results. Standard testing methods are still being discussed.

mentioned before and it is safe to assume that the copper-rich liquid predominates over the other in furnishing beta to a bronze around 25 per cent lead, if only because it is the first liquid to form. The reaction alpha + liquid $G$ = beta will continue until there is no more alpha or liquid, but the latter will evidently be exhausted first as it is being consumed by the formation of the second liquid, and besides, more alpha is being furnished. Consequently as a source of supply the liquid $G$, even being rich in copper, does not allow the beta reaction to progress very far. The other liquid, $H$, having a high lead content, has a depressing effect on the reaction line, hence its slope is toward *Pb* as the liquid is enriched in lead, and the beta precipitated from it is thrown out at a constantly falling temperature. The beta furnished by this liquid is little for the ordinary percentage of lead in bronze; but in any case beta freezes out as the liquids follow the line *B J*. When the liquid reaches $J$ a rapid reduction in temperature takes place with a small change in composition of the liquid. Finally at *P b*, if the liquid has not all been used up by the above reactions, the alloy becomes solid at 326 deg. C.

*B Pb C* encloses an area in which beta is the first solid to form should the composition of the alloy lie in this area. By precipitating this solid solution the liquid is changed in composition until it reaches the line *D Pb*, which represents a similar reaction to that at $B$ whereby beta + liquid = $Cu_3Sn$. This reaction continues as the liquid follows *D Pb* as long as both constituents of the reaction are present. If beta is used up before *P b* is reached the liquid will freeze further as in the next area. As before, at 326 deg. C., the freezing of lead will complete the solidification. Similarly the next line, *E Pb*, denotes the formation of CuSn from the liquid and $Cu_3Sn$, the latter being the first to freeze in the area *D Pb E*. Again, *E Pb F* gives CuSn as the first solid to be thrown out of the liquid. Should the composition of the alloy be such that in cooling the liquid reaches *F K*, there will be a reaction between the CuSn and the liquid to form tin, the composition of the liquid passing down the line to $K$. When the liquid is exhausted the alloy goes solid, but should it hold out until $K$ is reached a further reaction takes place: CuSn + liquid $K$ = solid lead + solid tin, giving the ordinary eutectic of lead and tin. Solidification continues down to $I$ as long as the liquid supplies the reaction. In a like manner *Pb K* represents the simultaneous freezing of CuSn and lead (instead of tin) and at $K$ the above reaction occurs again with the liquid and CuSn. In the area *Pb I K* lead freezes first, in *FKI Cu* tin, and along *K I* the eutectic of lead and tin. The point $I$ is the binary eutectic of lead and tin and also the eutectic of the system.

The effect of lead on the physical properties and microstructure of bronze is for the most part simple. At times a fourth metal is added to make the desirable properties more pronounced; this addition and the rate of cooling are factors very influential on the structure of the alloy, so there is usually a departure from the normal constituents shown by the diagram. Lead and copper form no compounds or eutectic (the 0.06 per cent Cu eutectic not considered) consequently no compounds or solutions of these two metals are found in the alloy when the cooling is slow. Under normal conditions the only difference between a high and a low-lead bronze is the amount of lead distributed throughout the mass after solidification, the lead merely retarding the final freezing to 326 deg. C. and giving the alloy the property of plasticity. Microscopically plastic bronze shows black patches of lead set in the ground mass of bronze (alpha and eutectoid), and in this respect it differs from most anti-friction alloys. The ground mass is harder in this alloy than the included particles. The application of this type of bronze is almost exclusively as a bearing, and for heavy work it is widely used.

The experiments conducted by the Pennsylvania Railroad are responsible to a great extent for our knowledge of the behavior of lead bronze under working conditions. For a long time the limit of lead was 15 per cent; more than this caused difficulties in the preparation of the alloy. This difficulty was segregation and the ternary diagram easily explains the reason. First, consider copper and lead alone. With lead from 35 per cent to 90 per cent, there are two liquids from which the crystallization starts, and these being of a different specific gravity there is a separation or segregation in the liquid state. Then there is an unequal distribution of the solids crystallized from these liquids. On the other hand with lead up to 35 per cent there is only one liquid from which the freezing starts and this trouble is reduced immensely as regards this particular cause of segregation. While an alloy with the percentage of lead as in the last case was more productive of good results than with more lead, still a good casting was difficult to produce because of the too rapid cooling. Then it was found that by introducing tin a more homogeneous product was obtained and this is explained by alpha taking the place of copper alone. However, in the early practice the amount introduced was small because of the further observation that the lower the tin (consistent with homogeneity) the more lead could be added to the copper. Here again the diagram furnishes an explanation by the more recent experimental determination that the 35 per cent saturation point decreases with the addition of tin, so that as this metal is added the outside limits of the two liquids are extended and segregation is more likely to take place. So far, the early difficulties with this alloy are explained by the diagram, but by refinements in the mixing, casting and heat treatment, the old limit of lead, beyond which poor results were obtained, has been increased so that 30 per cent is not uncommon now. By the mechanical manipulation of alloy making, solutions and compounds are often made to change their limits; but since a diagram cannot be made to cover all the various practices, one must be adopted that represents the changes under normal conditions and when equilibrium is established.

Segregation has been the cause of the failure of many alloys. But now that recent knowledge shows the cause for this the trouble has been successfully overcome, not so much by varying the proportions of the constituents, but by the proper handling of the alloy while being compounded, and having the best properties to start with. By learning from curves and thermal diagrams what will be produced for a given mixture, it is easier to foresee trouble and avoid it.

Among the addition metals found to aid in preventing this trouble, the principal ones are nickel, sulphur and phosphorus. One per cent of nickel is said to improve a lead bronze so that with unskillful handling good results and little sweating are obtained with lead at 30 per cent. Copper and nickel are quite soluble in each other in the solid state, so nickel has the effect of producing more alpha solid solution in addition to the regular copper-tin alpha. Also under certain conditions it might be all dissolved in the copper-tin alpha. By a somewhat different method sulphur (added in the form of galena), also decreases the probability of segregation. $Cu_2S$ is formed and the dotted half-circle enclosing the two liquids is flattened toward *G H*. The alloy "Allen Metal" contains sulphur as $Cu_2S$. Phosphorus affects the alloy in a different way. This metal is very often associated with lead bronze and alone with copper constitutes another class of bronze that will be dealt with later.

Phosphor-lead bronze shows, in addition to the other constituents, varying amounts of the hard compound $Cu_3P$, which in a measure offsets the softer patches of lead. It is not often desirable to counteract the softening effect of the lead, because a soft bearing metal that will take the wear is better than a hard mixture that wears the journal. But phosphorus causes a good casting to be made from the alloy and therein lies its principal advantage. For a number of years the standard bearing-metal used by the Pennsylvania Railroad for its car journals was of this composition: 79.7 per cent copper, 10 per cent tin, 9.5 per cent lead and 0.8 per cent phosphorus. The more recent tests caused the adoption of a metal higher in lead and lower in tin on which the comparative wear was some 13 per cent slower than the first standard phosphor-bronze. This metal has the composition: 76.8 per cent copper, 8 per cent tin, 15 per cent lead and 0.2 per cent phosphorus and shows about 24,000 lb. per sq. in. tensile strength as against 30,000 lb. for the old standard. Another discovery is the successful substitution of arsenic for phosphorus. The tendency since then has been to increase the lead more and more and now the alloy commonly sold under the name of "plastic bronze" contains 30 per cent lead, 65 per cent copper and 5 per cent tin. This alloy is very satisfactory, and stands up well even in heavy locomotive bearings and for cars of the largest capacity. A compressive strength of 15,000 lb. per sq. in. is claimed for it, but it has excellent anti-friction qualities.

Other than for bearing metals, lead affects bronze by giving it superior machining properties, and also the appearance of aging or so-called "Patina," a dull bronze polish appreciated in bronze statuary.

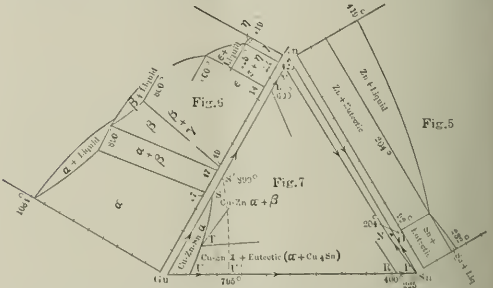
### The Effect of Zinc on Bronze

This phase of the subject could just as well be termed, "The Effect of Tin on Brass" and if so considered together the entire field of brass and bronze is included. Whereas others have written books on the history, physical properties and preparation of these two alloys, the ordinary metallurgist is not fully enlightened regarding their constitution. The microscope establishes at once the fact, the explanation and the proof of the constituents of brass and bronze, and the once dark secrets of alloy making are now being illuminated by the modern scientific searchlight. It is the purpose of the writer to illuminate a few of these dark points; but more important to the chemist and the average metallurgist is a brief description of the most prominent characteristics of brass and bronze, their appearance and the reason therefore. As mentioned before the subject is very extensive, and to deliver this kind of knowledge it would be best to follow the first heading of this division and further limit the discussion to high-tin bronze, with a few words about the other end of the series. Not that other compositions are not important but only bronze is under consideration here and the scope of this paper does not allow further elaboration.

Copper and tin is the base of the ternary (Fig. 7) as before. Zinc and tin (Fig. 5) form a very simple series without compounds and solid solutions. An eutectic point is at 8 per cent zinc and 204 deg. C.; to the left the solid alloy shows zinc and the eutectic, while to the right, tin and the eutectic are present. On the other hand zinc and copper (Fig. 6) give a brass consisting of a number of solid solutions depending on the composition. The series is more complicated than copper and tin, and there is less agreement among allographists as to the points of temperature and composition change, especially in the middle of the diagram. Consequently the two ends will be dealt with here; besides they are more important than the middle values. Three solid solutions are worthy of special notice: epsilon, of 14 per cent copper; beta, of 2.5 per cent copper, and alpha, of 37 per cent zinc.

First, a few of the principal constituents of this class of bronze.

The point of lowest temperature of the ternary is the eutectic of zinc and tin at 204 deg. C. The area *L M N* includes the solid solution epsilon (14 per cent copper) as the first solid to freeze, while the liquid is enriched until the line *M N* is reached. This is followed while the liquid plus epsilon gives solid beta, which with copper and zinc alone occurs at 425 deg. C (Fig. 6) and it is similar to the beta reaction in bronze. Should the liquid be exhausted before *N* is reached the alloy will go solid upon exhaustion, but if epsilon is used before the liquid, the liquid freezes further as in the next area *M Zn ON*. In the event both are present to allow the liquid to reach *N*, there occurs the reaction epsilon plus liquid *N* equals solid beta plus solid tin, which continues until final solidification.



FIGS. 5, 6 AND 7—TEMPERATURE-COMPOSITION DIAGRAMS FOR ZINC-TIN, ZINC-COPPER AND TERNARY

In the area *M Zn ON*, beta solid solution freezes first until the liquid reachese *N O* when beta and tin are precipitated side by side, similar to the ordinary eutectic. Finally the solidification is completed at *O*, the binary eutectic point.

CuSn freezes first in the area *R N P* and when the liquid reaches *N P* there will be a simultaneous freezing of CuSn and tin. At *N*, should the liquid reach there, will occur the same reaction as above with CuSn in place of epsilon.

The area *NO Sn P* yields tin as the first crystals and as before along *N O* the beta-tin eutectic completes the freezing.

As an example of a commercial alloy in the above areas one of the Lumen Bearing Company alloys of about 85 per cent zinc, 10 per cent tin and 5 per cent copper, is illustrative. This solid alloy shows dendrites of epsilon, the first to freeze, surrounded by envelopes of beta, which formed along the line *M N*, and small streaks of beta plus tin in the ground mass produced by the reaction at *N*.

Again Parsons' white brass, which may be represented by the composition, 30 per cent zinc, 65 per cent tin and 5 per cent copper, shows beta and epsilon as before, but a much greater proportion of the eta-tin eutectic ground mass, as the excess liquid allowed the reaction at *N*, and the formation of the eutectic along *N O*, to progress much further. The eutectic being softer than the other constituents, the alloy containing the most, as in the last alloy, will have a softer ground mass and less hard dendrites. Here is the difference in structure between this type of bronze and lead bronze. When the copper content increases several per cent above 8 per cent in a high-tin bronze, and 14 per cent in a high-zinc bronze, $Cu_3Sn$ and epsilon with little beta are introduced respectively. The former is detrimental to a good bronze and it is usually formed unwillingly by being included in the kernels of CuSn and thereby stopping the action which should continue (and does on slow cooling) until all the $Cu_3Sn$ has given place to CuSn.

Now in the general run of this type of bronze the copper jumps to above 80 per cent when the zinc is low. The intermediate percentages between 8 per cent and 80 per cent are seldom encountered for the reason that the compounds found in this range are mostly brittle. A great many alloys have their compositions in the area *S U Cu*. From Fig. 6 it is seen that the copper-zinc solid solution alpha is present up to 37 per cent zinc, and from Fig. 1 the copper-tin alpha up to 10 per cent tin. Therefore, *S U Cu* encloses an area in which there is present the combined solid solution, copper-zinc-tin alpha; that is, in the solid state, as copper-tin alpha is precipitated from the liquid state up to 25 per cent tin, but upon cooling gives the eutectoid, so that to give alpha only, the limit is 10 per cent (normally). The same is true for copper-zinc alpha which freezes first up to about 45 per cent zinc, but in the solid state copper-zinc beta may be introduced if the zinc is much above 37 per cent. The second line *S′ U′* shows the limits of alpha when freezing from the liquid. The point *T* may be taken as the dividing point between brass and bronze. On the zinc side, copper-zinc beta throws the alloy into the brasses. On the tin side, the presence of the eutectoid determines the alloy as bronze. The area between encloses a mixture of the two.

Consider, for example, an alloy of 88 per cent copper, 10 per cent tin and 2 per cent zinc. Normally this composition is just on the line of separation beyond which the eutectoid appears. The zinc is all in the solid solution alpha because it is a value far below the saturation point of zinc in copper. Slow cooling produces homogeneous grains of alpha, but if the reaction, alpha plus liquid equals beta, is not allowed to be complete the grains are surrounded by some eutectoid formed from beta, and the two will appear as concentric circles. Of course, this alloy is practically identical in structure to ordinary bronze; the zinc changing alpha only slightly. Also, the physical properties are not altered much, a slight gain in tensile strength and ductility being apparent as a result of the zinc.

With more zinc another class of alloy comes under consideration. Zinc around 40 per cent with little tin gives the structure of Muntz metal, which is so characteristic that other alloys of similar appearance are classed in the Muntz metal group. Tobin bronze, manganese bronze and a number of heavy bearing metals come under this classification, and, as far as their zinc content is concerned, they are strictly brasses and not bronzes. Tobin bronze, for example, containing about 59 per cent copper, 38 per cent zinc, 2 per cent tin and a small amount of lead, is in the solid a mixture of the ternary alpha and copper-zinc beta, while all the tin is in the solid solution alpha. A reaction at about 890 deg. C. produces the beta from the alpha and liquid.

From these examples it can be understood that in a true bronze or a true brass the small amounts of zinc or of tin remain in the solid solution alpha, and the presence of the eutectoid on the one hand, and beta on the other, determines the bronze or brass nature of the alloy. These amounts of zinc in bronze or tin in brass do not affect the appearance of the solid alloy—it still remains bronze or brass, but the physical properties change accordingly.

One of the principal effects of zinc on bronze is the greater ease of cold rolling and forging. And its advantages in sea water are well known, especially of Tobin bronze. This alloy has a tensile strength in the neighborhood of 76,000 lb. per sq. in. when rolled, but greater ductility is obtained with a little less zinc. The cast alloy may have a value somewhat less than this, while cold rolling increases it slightly. It must be said that this high tensile strength is obtained at the expense of some of the other desirable properties, ductility for instance. Annealing and quenching play an important part in this connection. If an alloy of, say, 30 per cent zinc is heated to about 700 deg. C. and quenched in water, some beta is retained which would otherwise be absent. Again, a composition in the alpha plus beta range, by the same treatment, is made to consist mostly of beta. If so much tin is present in a bronze that it is ordinarily brittle, quenching from above 600 deg. C. gives copper-tin beta and the result is a workable alloy. The main field of the alloys in the copper corner of the ternary, is strength and salt water uses; those along the tin-zinc side come more strictly in the class of bearing metals or "white metals," particularly the zinc corner. They are harder than the lead-tin-antimony-bearing metals and more adapted to heavy loads.

## The Effect of Phosphorus on Bronze

Phosphorus is added to bronze for either, or both, of two reasons:

1. As a deoxidizer; and, therefore, as it passes into the slag no phosphorus is found in the alloy on analysis.

2. For its beneficial effects; and then it is either, (*a*) all in solid solution, or, (*b*) in the form of the compound $Cu_3P$.

Normally phosphor-bronze contains a large percentage of copper and a very small proportion of phosphorus. Part of the copper-phosphorus diagram is given in Fig. 8. A definite, very hard compound, $Cu_3P$, is obtained with 14.1 per cent phosphorus which with copper forms an eutectic at 700 deg. C. and 8.25 per cent phosphorus. These figures are due to the investigations of Heyn and Bauer. Also copper is capable of holding phosphorus in solid solutions up to 1 per cent on long annealing. Fig. 9 shows the copper corner of the ternary diagram adapted from Hudson and Law's researches but with changes which, while contrary to their theory, seem to be more or less self evident.

Consider an alloy in the area *Cu V X;* alpha, holding a little phosphorus in solution, freezes first until the line *W X* is reached, then beta freezes by the familiar reaction as in bronze until *W* is reached. Here, should liquid still remain, occurs the reaction, alpha plus liquid *W* equals beta plus $Cu_3P$, until the alloy finally becomes solid. Then beta gives place to the eutectoid as usual below 500 deg. C. The final structure then is alpha dentrites surrounded by, and in a ground mass of, an eutectic-like structure of $Cu_3P$ and the eutectoid ($Cu_3Sn$ and alpha). The point *W* (81 per cent copper, 14.2 per cent tin, 4.8 per cent phosphorus, at 620 deg. C.) according to Hudson and Law is the ternary eutectic of the system, but as William Campbell puts it, it could be more truly called a reaction point whereby the liquid with alpha form beta, and the beta in turn forming the eutectic with $Cu_3P$ and causing final solidification. Besides upon further cooling, beta breaks up into the eutectoid and the final alloy (unless quenched) contains no beta. It might be said that the high-phosphorus alloys contain the compound $Cu_3P$ as a pseudo-eutectic mixed with the eutectoid of alpha and $Cu_4Sn$; but with little phosphorus present it is dissolved in the alpha. The line *V W* represents the solidification of alpha and $Cu_3P$ side by side until *W* is reached when the above reaction takes place again. In the area *V W Y*, Cu$_3$P crystallizes out first and along *V W* the changes are the same as explained before. Small amounts of phosphorus seem to lower the solubility of tin in copper from 10 per cent to about 5 per cent, even when annealed.

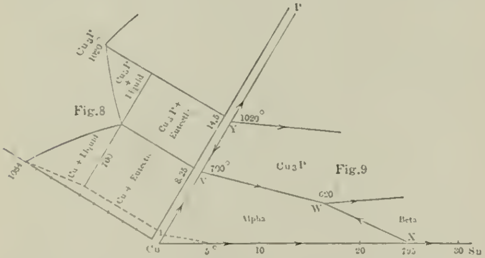
Then if the tin is present much more in amount than this, Cu$_4$Sn is introduced through the eutectoid, which, with the Cu$_3$P, gives two hard substances set in a softer alpha matrix. However, this matrix is harder than the lead-tin anti-friction alloys and therefore the plasticity of the former is less.

In general, the addition of phosphorus to bronze has the effect on the physical properties of greatly increasing the hardness and resistance to wear and for conditions requiring these qualities it surpasses all other alloys.

The other properties of the bronze, *i. e.*, the tensile strength, elastic limit and elongation, are impaired in proportion to the phosphorus added. Consequently, the phosphorus is kept low, relying more on its deoxidizing and cleaning powers to give to phosphor-bronze the good qualities it possesses.

The class of bronze in which both tin and phosphorus are low includes most of the commercial alloys and these show a certain degree of malleability and ductility. The upper limits in composition of these two metals for such properties may be placed at 8 per cent tin and 0.8 per cent phosphorus. Within these limits the phosphorus is held in solution in the solid alpha due to the long annealing which this alloy usually undergoes, and the result is a single homogeneous solid solution. Should this phosphorus limit be too great, so as to admit the possibility of forming Cu$_4$P, the tin hinders the action and further causes the compound to be distributed in finer patches throughout the mass. It is essential that if malleability is desired the hard substances Cu$_4$Sn and Cu$_3$P must be eliminated as far as possible. The commercial alloy frequently contains tin and phosphorus outside the above limits when hardness is not so detrimental to the particular use of the alloy. In fact, it has been found that other metals make up for the excess hardness produced by too much tin and phosphorus and by using such a metal to neutralize their hardening effects, the wide limits could be used to give other qualities and still give as a net result a comparatively soft alloy. Lead is nearly always present for anti-friction and softening purposes when the alloy is used in bearings. The purpose is to get the most suitable mixture of copper and tin to give strength, then harden and deoxidize it with phosphorus, and finally add lead to soften it somewhat and give the necessary anti-friction quality.

The alloy sold as phosphor-bronze has a tensile strength around 30,000 lb. per sq. in.



FIGS. 8 AND 9—TEMPERATURE-COMPOSITION DIAGRAM FOR COPPER-PHOSPHORUS AND PART OF TERNARY

## The Effect of Manganese, Aluminium and Iron on Bronze

In the first place, manganese bronze should be called manganese brass; and, again, a number of alloys sold under this name have no manganese whatever in them. Since manganese bronze is a name standing for strength, brass foundries turn out alloys and sell them under this name in order to market their product. Many of the reputable firms do this, which is admissible, as they have the strength to back their alloys, but it has been found that many manganese-bronzes have their strength only in their names.

In the composition of manganese bronze, aluminium is frequently of a greater percentage than manganese, so the modification could go still further—aluminium brass. Manganese and aluminium "bronze" are so closely related that it is difficult to discuss one without the other. It is true that the real aluminium bronze is still widely used for certain purposes and until the last few years it was a competitor of manganese bronze in the field of usefulness that the latter occupies now. It has been replaced, but in name only, by manganese bronze as the many desirable characters of this bronze are due largely to the aluminium it contains.

Manganese bronze dominates the field of combined strength and non-corrosive alloys. Monel metal is its only competitor—at a higher price. As a bearing metal it finds little application except under very light loads.

High-zinc brass gives unsatisfactory sand castings and therein lies the advantage and object of adding aluminium. Iron gives a high elastic limit to copper and zinc and hence the use of manganese as a carrier of the iron. Metallic iron melted with the alloy gives patches of ferrite which are hard and limit the machining of the metal. When introduced in the form of ferro-manganese this trouble is eliminated. P. M. Parsons was the first to determine the benefits of these added metals and although his patents have since expired, he introduced the alloy in England and later in the United States. His original mixtures have been changed very little.

The manganese bronze in use now has two compositions, one for sand casting and one for rolled sheets and forgings. The following will show about the average analysis and mixture:

| | Sheets and Forgings | | Sand Casts | |
|---|---|---|---|---|
| | Analysis | Founders' Mixture | Analysis | Founder's Mixture |
| Cu.... | 60.1 | 60 lb. (Ingot) | 56.0 | 56 lb. (Ingot) |
| Zn.... | 37.8 | 39 " (Pure Speller) | 41.5 | 43 " (Pure Spelter) |
| Fe.... | 1.3 | 2 " Steel Alloy | 1.2 | 2 " Steel Alloy |
| Sn.... | 0.7 | | 0.7 | |
| Mu.... | 0.1 | | 0.1 | |
| Al.... | .. | .. | 0.5 | ½ " (Ingot) |

Steel alloy: wrought iron 18 lb., ferromanganese (80% Fe, 40% Mn) 4 lb.; tin 10 lb.

The small proportion of manganese and the absence of aluminium in sheets is worthy of notice. When rolling and forging the alloy, better results are obtained with more copper and less zinc than is used in the sand casting mixture. Since both compositions give a Muntz metal structure, more copper will produce more alpha which is better adapted to being worked than beta. Aluminium is the beneficial element in the casting mixture, but since this alloy must be melted first in the proper order and cast into ingot bronze and then remelted for the final casting, it is eliminated in the rolling mixture which then only needs to be melted once.

Iron has an unlimited solubility in manganese and manganese has an unlimited solubility in copper; consequently these extra metals, together with tin and aluminium, are all in solution in the alpha. The copper and zinc percentages give the structure of Muntz metal so a diagram other than Fig. 6 is not necessary to explain the constitution of manganese bronze.

The reported strength values of this alloy vary considerably. The following, however, may be taken to represent averages from the above mixtures:

| | Cast Bars | Cold Rolled |
|---|---|---|
| Tensile strength.......... | 70,000 lb. per sq. in. | 95,000 lb. per sq. in. |
| Elastic limit ............ | 30,000 " " " " | 80,000 " " " " |
| Elongation in 6 in........ | 18 per cent | 12 per cent |

Another type of manganese bronze is used as a resistance alloy. It is white, due to 18 per cent manganese, and contains also about 67 per cent copper, 13 per cent zinc, 1 per cent aluminium and a little silicon. Its tensile strength is around 40,000 lb. per sq. in. for castings but its ductility is low. As to its resistance, it is claimed that 400 ohms per mil foot is a good average, while German silver for comparison, has about 180 ohms.

True aluminium bronze has many advantages that place it in a field of usefulness that cannot be invaded by managanese bronze. The alloy has as its prominent characteristics a low specific gravity and the ability to make sound castings from bronze. But to offset these qualities, the casting shrinks conderably, has low ductility and possible brittleness. It seldom contains more than 11 per cent aluminium. Part of the copper-aluminium equilibrium diagram is given in Fig. 10. It is somewhat similar to the left side of the copper tin curve, alpha holding 7.5 per cent of aluminium in solid solution, and the eutectoid point is at about 11.5 per cent aluminium. The best alloy contains alpha plus beta, obtained by quenching when the aluminium is between 7.5 per cent and 11.5 per cent. On either side of this range of composition, or when the eutectoid is present, the alloy is either weak or brittle. Eleven per cent of aluminium and 90 per cent copper is about the best composition, tests of which give around 80,000 lb. per sq. in. tensile strength. More aluminium causes excess brittleness, while less makes the alloy too weak, as for instance with only 1 per cent aluminium, 25,000 lb. is obtained. By introducing tin the alloy does not seem to be improved; *i. e.*, 88 per cent copper, 6 per cent aluminium and 6 per cent tin gives nearly 65,000 lb. tensile strength, but greater ductility. The gas engine is responsible for the extensive use of an alloy high in aluminium. About the best of this class of alloy is 92 per cent aluminium and 8 per cent copper, to which some founders add a small amount of nickel A tensile strength of 18,000 lb. per sq. in. is near the average value, but its principle advantage lies in its low specific gravity of about 2.8. It withstands repeated vibrations very well, much better than a similar alloy with the copper replaced by zinc, which has more strength.

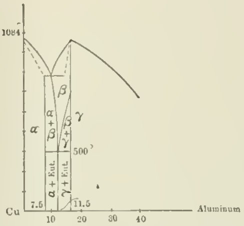


FIG. 10—PART OF COPPER-ALUMINIUM EQUILIBRIUM DIAGRAM

Durango, Colo.

**South Dakota made its record yield of metal in 1912,** in which year the gross value of gold, silver, copper and lead was $8,019,370. In 1913 the yield was valued at $7,424,333 from 30 producing mines, including 10 placers. There was 1,895,445 tons of ore treated in the state, yielding an average recovery per ton of $3.81 in gold and $0.052 in silver. The Homestake mines and mills produced and treated 1,540,961 tons of ore, yielding bullion valued at $6,186,652, or $4.01 per ton.

# Notes and Observations on Ore-Treatment at Cobalt, Ontario, Canada

BY H. C. PARMELEE

Ten years have elapsed since Cobalt made its first contribution to the silver production of the world. Within that period the shipment of silver ores and concentrates has increased in value from $136,217 in 1904 to $16,555,001 in 1913.[1] Shipment of bullion produced in the district increased from a value of $501,815 in 1910 to $5,895,449 in 1913. In the latter year Cobalt was credited with 14 per cent of the world's production of silver.

Mining at Cobalt always has been characterized by many spectacular features which have become a matter of common knowledge. The richness of the ore, the large masses of native silver, the deposits of cobalt and nickel minerals, and the development of an immense mining industry in a region supposed to be valuable only for agriculture and lumbering—these features have characterized Cobalt. Mining has indeed been unique, but no less striking have been the recent metallurgical advances, resulting in the accomplishment of things considered improbable, if not impossible. Nor is the end yet in sight, for there are indications that Cobalt is entering on a period of progress in metallurgy that will develop further novel processes and methods. Large problems still exist and good men are attacking them.

### Present Situation and Future Prospects

Leaving out of consideration for the present the specific technical problems at Cobalt, the general economic situation is about this: In the early years of its history the district produced principally high-grade silver ore.

Other valuable minerals, chiefly of cobalt and nickel, existed in the ore, but their value was not comparable to that of the silver, and they received but littel consideration, metallurgically speaking. Silver was the metal of chief value, and the ores were shipped and smelted for its recovery. Cobalt, nickel and arsenic were by-products of little economic value to the producer.

Low-grade ores also were developed, and these were enriched locally by ordinary methods of water concentration. The concentrates, too, were shipped from the district and smelted at other places in Canada and the United States. With the gradual and inevitable exhaustion of the high-grade ores, there was an increase in production and concentration of low-grade material. This tendency has been marked in the last few years: in 1912 the concentrating mills treated 390,473 tons of crude ore, and in 1913 they handled 531,548 tons. The prospect for the current year is that a still greater tonnage of low-grade ore will be enriched by concentration.

One of the most clearly defined elements of the situation, therefore, is that ore-dressing is a factor of increasing importance in the district. Lower grades of ore will be mined, old mine dumps will be treated, and every effort made to conserve the diminishing resources just as far as mechanical methods can be applied.

This means an increased production of the table concentrates, coincident with a decreased output of high-grade ore, and has an important bearing on the future of metallurgy in the district, as will be pointed out later.

---

[1] Statistical data are quoted from the 1914 report of A. A. Cole, mining engineer to the Temiskaming & Northern Ontario Ry. Commission. This report is published annually and distributed by A. A. Cole, Cobalt, Ontario, Canada.

### Local Production of Bullion and By-Products

Another feature of the metallurgical situation, which has been recognized by the progressive companies in the district, is the desirability of producing bullion at the mines instead of shipping ores and concentrates to smelters. The local output of a finished product, salable to mints or other consumers of silver, and the recovery of valuable by-products such as cobalt, nickel and arsenic, would be preferable to the shipment of raw material requiring further treatment, providing economic methods could be devised that would gain for the producer the profit which it may be assumed the smelter is making. Judging from the research now under way, it may be safely predicted that the production of silver bullion and by-products will increase, and shipments of raw material decrease considerably in the next few years. The general tendency toward the increased local treatment of ores by all methods—concentration, amalgamation and cyanidation—is shown by the following figures: for 1912, 455,517 tons; for 1913, 664,845 tons.

The reduction of ore to bullion and the recovery of some by-products has been an accomplished fact at Cobalt for several years past, but has been confined mainly to the treatment of high-grade ore and tailings from concentration. By far the greater proportion of the tonnage mined is concentrated, but the local reduction of table concentrates has not been as extensively practiced as it will be.

A scheme of amalgamation in strong cyanide solution is used for high-grade ore, while low-grade ore and tailings from concentration are treated by cyanidation only. The Nipissing company is successfully cyaniding ores similar in grade and character to those ordinarily concentrated at other mills; the Dominion Reduction Company is cyaniding concentrates and tailings separately; the Buffalo company is reducing jig and table concentrates with high-grade ore, and both the Buffalo and O'Brien are cyaniding slime tailings from concentrates. Details of these methods will be referred to later. The following tabulation shows the reduction methods used and materials treated.

| Company | By amalgamation and cyanidation | By cyanidation |
|---|---|---|
| Nipissing | High-grade ore and jig concentrates | Low-grade ore. |
| Dominion Reduction | Table concentrates | Slime tailings from concentration. |
| Buffalo | High-grade ore, jig and table concentrates | Slime tailing from concentration. |
| OBrien | | Slime tailings from concentration. |

### A Complex-Ore Problem

The recovery of the valuable metals from the ores and concentrates of the Cobalt district presents a neat metallurgical problem, particularly with reference to table concentrates. Here we have truly a "complex-ore problem," although different in kind from what is usually understood by that term in the western United States. In order to appreciate the condition at Cobalt, consider the list of the principal minerals contained in the ores: native silver, sulphides of silver and nickel, arsenides of nickel and cobalt, arsenate of cobalt, sulpharsenides of iron and cobalt, antimonide of silver, sulphantimonite of silver, and some others. These minerals represent at least four metals of economic importance—silver, cobalt, nickel and arsenic—the recovery of which offers an opporunity for research and operative skill.

The reduction of table concentrates presents a different problem to that offered by high-grade ore. Comparatively little difficulty is experienced with the latter, as the silver is mainly in the native state and yields almost a complete recovery by amalgamation in cyanide solution. Table concentrates, however, differ in containing a large proportion of the complex silver minerals and a smaller proportion of native silver. This mineral content is the main factor in the problem of reducing table concentrates and recovering therefrom the several metals of economic value.

Essentially two lines of attack are being made on this problem—by amalgamation and by cyanidation. Each is marked by a high consumption of the chemical employed and involves some scheme for its recovery.

Amalgamation will yield silver bullion and a residue containing principally cobalt, nickel and arsenic. There will be a comparatively heavy chemical consumption of mercury, due to the formation of mercury sulphide which remains with the residue. This necessitates a treatment of the residue for recovery of mercury. Such a process is in use at the Buffalo mill, and as soon as operating data are obtained we expect to be able to present details of the process and the metallurgical results.

Cyanidation of table concentrates, on the other hand, is being investigated by the Nipissing company. No details of results have been made public, but it can be surmised that a high chemical consumption of cyanide will ensue, and that some method for its regeneration and for the recovery of metals, other than silver, taken into solution, will be a part of the process. This research should add greatly to our knowledge of cyanide chemistry. It is expected that a process will be developed whereby high-grade ore concentrates can be treated by cyanidation only, eliminating amalgamation as now practiced by this company.

The outcome of these two different lines of research will be awaited with interest, for their success means much to the Cobalt district in the local production of bullion. The ultimate superiority of one method over the other must be determined by the metallurgical and economic results and the mechanical requirements, as shown in practical operation.

Chlorination has been proposed for the treatment of these ores, and some experimental work has been done by interested parties. Mr. John L. Malm, of Denver, made tests several years ago according to a method[2] which he has advocated for complex base-metal ores of the western United States; and in our last issue we recorded the details of a process[3] patented by Mr. Oscar Dyckerhoff, of Karlsruhe, Germany, specially applicable to Cobalt ores.

### Retreatment of Sand Tailings from Concentration

The sand tailing dumps at some of the concentrators in Cobalt represent an asset worthy of conversion into money. The successful treatment of this material constitutes another metallurgical problem which is being investigated by several companies, and it is likely that within the next few years a large tonnage of this material will be treated by cyanidation.

The silver content of sand tailing will range from 4 to 8 oz. per ton. In the opinion of engineers thoroughly familiar with conditions and competent to judge, there is more 6 to 8 oz. tailing than is generally admitted. This is particularly true of earlier practice. Exceptions exist as in all such cases, and there are some sand dumps containing only 3 to 4 oz. silver per ton.

Under present conditions it is unlikely that any attempt will be made to retreat these lower-grade dumps, but enough work has been done on others to indicate the advisability of erecting the necessary grinding and cyaniding plants for their treatment. Dump sampling is not difficult, particularly where the tailings have been stacked and not run into the lakes. The piles are quite uniform in value, and accurate estimates can be made of their metal content.

---

[2] This journal, Feb., 1914, p. 128.
[3] This journal, June, 1914, p. 412.

Generally speaking these sand tailings, and very low-grade ores too, require fine grinding for the liberation of metal and mineral from the enclosing gangue. For this reason it is unlikely that further concentration would be an effective treatment. Screen analyses of sand dumps show a marked concentration of silver in the finest portion, say 200-mesh and finer, while the grades from 20 to 150-mesh, inclusive, will assay about the same as the whole sample. The following tabulation illustrates this condition, the figures representing a fair average of sand tailing containing about 6.5 oz. silver per ton.

| Mesh | Per Cent by Weight | Oz. Silver per Ton |
|---|---|---|
| + 20 | 30 | 6.5 |
| + 40 | 35 | 6.2 |
| + 60 | 21 | 6.2 |
| + 80 | 7 | 5.8 |
| + 100 | 3 | 5.7 |
| + 150 | 2 | 6.3 |
| + 200 | 1 | 8.5 |
| — 200 | 1 | 28.6 |

Similar results, though with less striking concentration of metal in the finest portion, are obtainable from 3 and 4 oz. sand tailings.

The cyanidation of this material seems to offer no serious obstacles, when ground so that about 90 per cent. of the solids will pass a 200-mesh screen. By grinding in a tube mill in cyanide solution, and agitating the thickened pulp, an extraction of 90 per cent. is possible. A system of continuous counter-current decantation following agitation would complete a very simple and effective plant. The finely ground material is sandy and settles readily, so that from 5 to 7 sq. ft. of settling area per ton of dry slime is quite sufficient. The cost of cyanide would be from fifty to sixty cents per ton, and the total cost of treatment probably not more than $1.75. Thus on material of $3 to $3.50 gross value, a fair profit could be realized, but 4-oz. tailings would not much more than pay for treatment.

Some interest is being taken also in the possibility of applying flotation to reground sand tailings, but only a few tests have been made. The point to be determined in this connection is whether the use of an intermediate concentrating process, followed by cyanidation or amalgamation of the concentrates, would yield a higher economic return than could be obtained by direct cyanidation as just outlined. The apparent advantage of flotation would be the greatly reduced volume of material to be treated in the final process, due to the rejection of the bulk of the gangue in the flotation process. This is a line of investigation that may be pushed further, as there are several types of flotation processes, one of which might be found specially applicable.

### Cyanidation of Slime Tailings from Concentration

At two mills in the district, slime tailings from concentration are being cyanided. According to the report of Mr. A. A. Cole, previously mentioned, the Buffalo company in 1913 cyanided 11,744 tons of slime and produced 110,505 oz. silver; the O'Brien mill treated 39,663 tons of slime, producing therefrom 228,544 oz. silver. These facts suggest that the slime tailings now being wasted from concentrators are more valuable, ton for ton, than the sand, and that a recoverable asset is being neglected. Not only is it being neglected, but in some cases it is being put beyond the possibility of ultimate recovery by being discharged into lakes instead of being impounded.

There are several reasons why this preventable waste is to be deplored. In the first place a great deal of energy has been expended in grinding this slime, so that most of it is in a condition suitable for cyanidation, and would require but little more grinding. Again comparatively simple means are at hand for applying the cyanide process, and the additional cost of machinery, chemicals and labor would not be prohibitive in view of the possible recovery. If it is regarded as feasible to regrind and cyanide a 6 to 8 oz. sand tailing, it would seem possible to cyanide slime tailing of the same value which is already ground much finer, and requires practically only agitation for solution of the silver. Finally, this further treatment of slime offers a simple expedient for adding to the recovery effected by the concentrator, and should appeal to progressive metallurgists. Perhaps concentration by flotation might be applied to this material, and in that event the pulp would be ready for treatment after a preliminary thickening. Economically, however, it is likely that cyanidation, with its production of bullion, would be preferable to flotation and the recovery of concentrates requiring further reduction.

At the O'Brien mill the ore is first jigged in water and the jig tailings are then crushed in stamps in cyanide solution. Hardinge and tube mills are used as regrinders, and Deister tables make a further concentration of the reground pulp. Slime is finally separated by Dorr classifiers, thickened, agitated and filtered. The cyanide department at the Buffalo mill is an adjunct to the concentrator, and the scheme of treatment includes well known methods of thickening, agitating, filtering and precipitating.

Other companies in the district are now considering cyanidation as a logical extension of their work in concentration. Until methods are adopted which eliminate concentration altogether, this idea is an excellent one and worthy of wider use. The fullest credit is not reflected on the metallurgist as long as an economically recoverable asset is being wasted. In this problem, of course, are involved the life of the mine, the daily mill tonnage and the cost of additional plant.

## The Story of Mining and Metallurgy

At the fiftieth anniversary of the School of Mines of Columbia University, on May 29, 1914, Mr. T. A. Rickard, as the official representative of the Royal School of Mines, London, made a brilliant address on the calling of the mining engineer and metallurgist.

Mr. Rickard spoke as follows:

"It is a common saying that agriculture and mining are the two basic industries. When man rose above the brutish individualism of his primordial state and began to develop the social instinct, he turned to the soil, in order to win food for his family. He paused in his migration, the soil held him; it gave root to his rudimentary community; it gave him the chance to enlarge his energies. His tracks became highways; his rivers, avenues of trade; and as his traffic expanded, so his imagination widened, until, out of the crudities of communal development grew the complexities of civilization.

"But the nomadic habit lingered; the spirit of the hunter survived in man; a wanderer and a wonderer he stood beneath the starry dome of the forest arch not knowing whether he were the guest or a captive in the domain of Nature. The hills beckoned; the seas called; the more venturesome left the tents of the tribe in search of material wherewith to fashion their implements. They sought iron for weapons, copper for tools, gold for ornament, and found them in various guise in the earth under their feet. They became miners. To those who delved successfully came power. Throughout the ages the more energetic and adventurous broke from the plough and forsook the cattle in order to explore and to exploit. They brought the metals from which the artificers fashioned engines of power and machines of intelligence. They won the materials for a social structure that, based on stone and built in iron and copper, soared in many-storied tracery of steel to towers radiant with light and vibrant to the sky—towers so far above the common ground that man almost forgot his lowly origin and claimed kinship with the stars.

"The story of mineral exploration and racial migration is peculiarly the heritage of our people, the Anglo-Celts. It is the *motif* that runs through the drama of English and American history, more particularly during the last hundred years. Even in its barest outlines it serves to suggest that the miner is the pioneer of industry and the herald of empire.

"The first social organizations around the shores of the Mediterranean sent their prospectors to the hinterlands of Europe, Asia, and Africa. The gold of Ophir, the copper of Sinai, the silver of Laurium were part of the web and woof of those early civilizations. The mines of Iberia gave Hannibal the sinews of war against Rome, and the gold of Davia strengthened the resources of Rome under Trajan. But the greatest adventure was that of the Phoenicians who passed through the Pillars of Hercules into the western ocean in order to reach the far Cassitorides, the tin islands that in turn were to produce those Cornishmen to whom the world is one big mine. After Carthage and Rome, in turn, had been overthrown, the mining industries of the known world were disorganized. Desultory operations persisted in Hungary, Spain, and Saxony, but the Middle Ages to the miner were as dark below ground as above. Even the discovery of America, which marked the beginning of a new world movement, was not connected with a real advance in mineral exploitation, although associated with the winning of gold and silver. It is true, the wave of Spanish conquest broke over the American continent, penetrating the treasure-vaults of Mexico and Peru. But the Spaniard devastated, he did not develop. He gathered the harvest that the patient Indian has sown by the laborious toil of centuries. Cortez and Pizarro were filibusters, not explorers; they were pirates, not miners. The *conquistaderes* were no pioneers of industry; behind them arose the smoke of ruin and the dust of destruction. Even the great sea-captains of Elizabeth were but the sequel to an epoch of spoliation. After them, and in their wake, across the sea, came the men who from Cornwall and Devon, from Saxony and the Harz, brought the technique of mining to the new world, applying it peacefully to the mineral development of Mexico, Peru, and Chile, all along the regions previously ravaged by European freebooters.

"But the great era of mineral exploration came with the discovery of gold in Australia and California. It was the prelude to a worldwide migration, an enormous expansion of trade, a tremendous advance in the arts of life, and the spread of industry to the waste places of the earth.

"The colour of energy began to tint the blank spaces on the map. The western half of the North American continent, all of Australia, the southern half of Africa, the northern half of Asia, were invaded, penetrated, and explored by those in search of gold, of other metals, and as each successive mineral discovery was made by the miner he called upon his fellows to come and take a hand in the good work. He was the scout far ahead of an army of development. Trade follows the flag, it is true, but the flag follows the pick."

Mr. Rickard then told of the finding of gold in California by James W. Marshall on January 24, 1848, and of the sudden rush of the gold seekers to the Pacific Coast which is so well known in the history of California and which resulted in the production of $81,294,700 in gold in 1851, giving details of the subsequent history of the industry. Among those who were first in those fields was E. H. Hargraves, an Australian, who was led by the analogy of geologic conditions to those in his own country to suspect the occurrence of gold there, and he returned to his home in New South Wales, where on April 3, 1851, he announced the discovery of gold in Australia. The rush to those gold fields was great and in 1853 the gold production there was $54,882,000. The first diamond was found in South Africa, he said, in March, 1869. The history of the de Beers and Kimberly mines, the discoveries in other regions of the Rand and in the West African gold fields, the story of the Yukon and Klondyke were next told. After speaking of the great work of prospectors in the development of the countries they visited, Mr. Rickard concluded by saying:

"After the prospector has come the mining engineer. The scout has gone in advance of the captain of industry. Those of you that have crossed the range in winter know how the loader breaks the trail by leaving footprints into which his followers tread, step by step, greatly to the safety and ease of their travel. That is what the mineral explorer has done for the mining engineer. That is what the mining engineer has done for those behind him. Some of you have been prospectors as well as engineers.

" 'Have you known the great white silence, not a snow-gemmed twig aquiver?
Have you broken trail on snowshoes; mushed your huskies up the river?
Have you marked the map's void spaces,
Felt the savage strength of brute in every thew?'

"Again I ask you to recall how you threaded the pathless forest on your way to examine a new mineral discovery. On the trees at intervals you have seen that the bark was chipped. The trail has been 'blazed' by the prospector, making it easy for you and others to follow. That is what the miner has done in a larger way for civilization. He has done it with geographical exuberance and equatorial amplitude. From 'the stark and sullen solitudes that sentinel the Pole' to the 'steaming stillness of the orchid-scented glade' in the Tropics, he has left his mark. You know that. No need for the prospector to complain to you, like Kipling's explorer:

" 'Well, I know who'll take the credit: all the clever chaps that followed—
Came a dozen men together—never knew my desert fears;
Tracked me by the camps I'd quitted, used the water holes I'd hollowed.
They'll go back and do the talking. They'll be called the Pioneers!'

"No; not by the men of the Columbia School of Mines, who have shared the prospectors' camp-fire, his blankets, his flapjacks, and his beans. You will give credit to whom it belongs. To the man with the faith of a child and the heart of a viking, to the man who has tramped and toiled until he heard "the mile-wide mutterings of unimagined rivers and beyond the nameless timber saw illimitable plains"; to the miner who has crossed the last range of all and lies in the only prospect-hole he could not dig; to the man who was the herald of empire and the pioneer of industry; to him who 'blazed the trail.' "

# Is There a Complex-Ore Problem?

## A Symposium on the Economics and Metallurgy of Mixed Base-Metal Sulphide Ores, Showing Present Status and Future Prospects of This Branch of Ore-Treatment

In our May and June issues we presented a number of replies received in answer to a set of questions propounded to leading metallurgists on the general subject of complex ores. The interest manifested in this inquiry has been all that could be expected, and indicates how widespread is the problem that is being attacked by many different methods and from different angles. We present below two additional replies that have been received, together with an editorial summary of the subject. For convenience in following the trend of the replies, the questions are here reproduced.

1. Is there a "complex-ore problem," and what, in your opinion, constitutes a "complex" ore?
2. Would such ores be amenable to present methods in the hands of skilled operators, or is there a need for new methods of treatment?
3. Do you believe there are many mines now idle which could produce a considerable tonnage of such ore if suitable methods of treatment were known?
4. What element or quality of such ores makes them refractory to present processes?
5. What methods or processes do you regard as probable solutions of the problem (mechanical, hydrometallurgical, electrometallurgical)?
6. To what extent would microscopical examination of such ores be of material assistance in suggesting proper methods of treatment?

**F. L. Clerc.**—The symposium to which we are invited for the discussion of the complex-ore problem has proved a social success. Let us all raise our glasses, whether they be eye-glasses, laboratory beakers, microscopes or telescopic lenses, to pledge ourselves to contribute to its solution; and in honor of the sentiment of cordial cooperation, drain the new life typified by the generous juice of the grape. My rôle must be mainly to second the motion, or endorse the opinion, of the last speaker. The subject has been covered so fully that any amendment I will suggest appears to me to be in the way of more fully expressing opinions already set forth. It is always of interest to know just how far such support and endorsement goes. This can be shown by a categorical answer to the questions submitted.

1.—Yes, there is a complex-ore problem, a general one: The maximum utilization of the valuable constituents of mixed mineral substances, and the discovery of uses for the other constituents. A complex ore is one in which the mineral or minerals containing one valuable constituent are intimately entangled with minerals containing other valuable or, at present, worthless constituents.

2.—All known mineral substances and compounds can be separated by laboratory methods. Metallurgical operations are modifications and extensions of laboratory manipulations. The question of profit involved may be answered Yes, if the skilled operators can live in the meantime.

3.—The lean-ore problem presents itself at every working mine, as attested by the mine dumps and piles of tailings and polluted streams. If these complex mixtures could be utilized, the tonnage from mines now working would be greatly increased. These mines could be opened and worked to better advantage, and the danger of losing the bonanzas by too contracted workings would be lessened. Doubtless there are many abandoned mines and discovered mineral deposits which can be profitably worked if the valuable constituents of the leaner complex ores can be made useful.

4.—The element which makes complex ores refractory to present processes is that one of least value commercially; that is, after deducting the cost of treatment. The quality which contributes to refractoriness is the intimate entanglement of minerals which require different treatment for the extraction of the valuable metals they contain.

5.—All of the methods or processes mentioned have their application to special cases of the general problem. They are being constantly improved in practice. All mechanical separations of ore containing one or more valuable constituents are stages of metallurgical treatment; even selective mining, crushing, hand-sorting and any method of separation or concentration. Transportation from mine to mill or smelter is included in the handling of ores, and a saving in any of these items renders increased amounts of complex ores amenable to existing processes for utilizing valuable constituents. My own experience leads me to believe that there is an opportunity for the wider use of pyrometallurgical concentration—either with carbonaceous smelting or sintering, pyritic smelting or electrothermic smelting—and in the last few years I have advocated the use of such processes for the preliminary treatment of the zinc carbonates and silicates of Leadville, and other base-metal ores.[1]

All of those who have been present at this symposium appear to be in harmony in the opinion that whether any broken mass of rock is or is not an ore, depends on where it is, who owns it, and on the current market price of its valuable constituents, as well as on the skill and knowledge of the metallurgists who handle it. Among the environments necessary for the survival of metallurgical enterprises may be mentioned sufficient capital, a favorable location and good administrative and executive management. Any enterprise may fail if any one of these conditions is lacking.

6.—A hand magnifying glass is generally sufficient to determine how far mechanical processes will apply, or, if not, a small-scale test can be made in a metallurgical laboratory. In hydrometallurgical processes it is often of importance to know just how the various constituents are associated in the ore. In this case microscopic examination is very useful to supplement chemical analysis. But such examinations and small-scale tests need only be made once for a given ore: that is, until there is a change in the material treated. Yet I have known of cases where silicate of copper, existing in very small quantities in a silicious gangue, has been treated under the supposition that the copper existed as carbonate; also of silicates of zinc which were supposed to be carbonates; and of gold in sulphides which was supposed to be free. In short, no available means should be neglected to learn all we can about the ore to be treated before we reach or pronounce a judgment. From the nature of the case, such microscopic examinations of small-scale tests can best be made by specialists who have exceptional training and laboratory equipment.

Estes Park, Colo.

* * *

**L. D. Godshall.**—1.—There is a complex ore problem. In my opinion a complex ore is any ore which contains a valuable metal or metals difficult to save. Such complex ores may include:

---

[1] The Utilization of the Zinc Carbonates and Silicates of Leadville, Colo., *Proceedings* of the Colorado Scientific Society, Vol. X, pp. 85-98. A Zinc Retort with a Copper Bottom, this journal, Aug., 1912, p. 463. Igneous Concentration of Metallic Values from Mixed Sulphides, this journal, April and May, 1914, pp. 250 and 307.

(*a*) An intimate mixture of base-metal sulphides containing lead, zinc, iron and sometimes copper, with or without gold and silver, a small or large amount of gangue material, and presenting more or less difficulty in the concentration or separation of the various minerals by reason of crystalline texture or insufficient variation in specific gravity of the minerals to be separated.

(*b*) A single metal like gold or silver, in a gangue too silicious or expensive for direct smelting, but presenting serious difficulties in concentration, amalgamation or cyanidation, by reason of part or all of the metal being contained in a mineral too minutely disseminated, or easily slimed in crushing, or by having present in the ore other constituents like manganese, tellurium, etc., which may interfere with the process to be used.

2.—Many of these so-called complex ores are amenable to present methods in the hands of skilled operators. There is always a need for new methods of treatment as well as a need for improvements in present methods. The need for new methods can be illustrated by the present work at Chuquicamata; the need or value of constant improvement in present methods, by the slime treatment at Anaconda.

3.—Large mines or extensive deposits of any ore are scarce, and inasmuch as large ore-bodies present great commercial possibilities if economically treated, much more effort has been expended trying to solve the problem of correct treatment for such ores than for small and relatively unimportant bodies of ore. There are many mines capable of producing from 10 to 50 tons of ore per day if suitable methods of treatment now known were properly used.

4.—The nature of ores which are commonly termed refractory should, I think, be considered as apparent and real.

Many ores commonly termed "refractory" are so only because of inefficiency in the treatment applied to them, due to ignorance and bad management.

With some ores the refractory nature is real, and evidently not to be overcome by means of present known methods. Such instances would represent the extremes as described in the above definition of a "complex ore."

5.—In the comparatively few cases representing the extreme refractory ores, it seems evident that we must look for an improvement in our present methods of separation, mechanical or chemical, by fire or electricity, or else discover methods or processes not yet existent.

For the great majority of so-called refractory ores found all over the West in mines capable of producing, as above stated, from 10 to 15 tons per day, we must look for greater efficiency with our well known processes of today. To obtain this greater efficiency the small operator must be educated to seek the assistance of experienced metallurgists and engineers in order to get *started* properly. The large company or the large property will have talent and capital at hand to solve almost any difficulty capable of being solved, and one or half a dozen failures will not prevent the big problem from final solution. With the small operator the case is very different. In the first place he has not the capital necessary to retain, for any great length of time, the high class engineer or metallurgist, and one mistake often puts him and his company out of commission. It is also a well known fact that the small operator who can least afford to try new-fangled methods is in very many cases the very first to do so. There are numerous monuments in every camp in the West illustrating this sad feature.

The difficulty in successfully handling a small output is very great, and recognized to such an extent that large companies will not consider small properties on account of the difficulty in keeping operating expenses down. It is possible to build, and I believe the near future will see, small plants as complete and almost as economical as our large ones; and when so built are equipped with the machinery and process *adapted to the ore*, and operated with the same conscientious care and detail as the large plant, we will consider many of our so-called complex ores anything but complex.

6.—I consider microscopical examination simply an aid to the visual examination of the ore. In concentration or separation it is necessary, of course, to have the crystal of the mineral we aim to save or separate free from the gangue or other mineral. If the microscope shows crystals of a certain size, we can crush the ore to that size, or if the crystals are so small that the freeing of same would require the practical sliming of the ore, we know before we make the attempt that concentration or mechanical separation will not be successful.

Tecopa, Cal.

### Editorial Summary

Impressions sometimes become settled convictions without sufficient warrant or evidence, and occasionally it is worth while to stop and make inquiry into a condition to see to what extent current opinion represents the truth. For some years past it has been a simple expedient to attribute depression in the western mining industry to "complex" ores for which no suitable method of treatment was known; at least this has been assigned as one of the contributing causes. "Complex ore" became the ready excuse for idle mines, lack of ore and unsuccessful mills, as well as the convenient explanation for a multitude of metallurgical sins.

We are not even intimating that really complex ores have not been discovered, or that they do not still present problems in metallurgy; but it seemed to us quite likely that some phases of the situation had been overstated or misrepresented through ignorance, while the true and more hopeful aspect of the case had not been expressed. In other words, it seemed likely that some of the general and popular impressions regarding the complex-ore problem had been created by radical spirits who either were not aware of, or did not appreciate, the constructive work of those who viewed the situation more conservatively.

Believing that a widespread public expression of opinion on the subject from many different points of view would be helpful and valuable, we sought the cooperation of prominent metallurgists and have presented their views. That there is striking unanimity in their attitude on some points, and but little diversity of opinion throughout, suggests the belief that we have secured a fair composite view of the whole situation. In geographical distribution the replies cover the whole country; in personnel of contributors they represent diversity of viewpoints and interests.

1.—All are agreed that there is a complex-ore problem, having reference to the economic treatment of mixed base-metal sulphides containing gold and silver. Several contributors emphasize the fact that there are many such problems instead of one; that neither ores nor processes are twice alike, and that each must be considered as a separate problem. Mr. Thomson considers the problem less serious and not as general as is commonly supposed, having in mind no doubt the exaggerated ideas as to the available quantity of refractory ores. In this he is supported by Mr. Swart who regards the problem as not wholly metallurgical, but closely related to the economics of mining—"the location, size and character of the ore-bodies." This takes the burden partly off the metallurgist who, in Mr. Swart's opinion, will successfully treat the ore "if there is enough of it." Mr. Bleecker voices a similar sentiment, and at the same time casts reflections on the alleged abundance of complex ores, when he says that "if the mine is not exhausted by the loss of this quantity of ore" (necessary to make a test) there is hope of solving the problem. Mr. Clevenger, on the other hand, viewing broadly the economics of metallurgy, believes that the problem always is with us "so long as the percentage of extraction is below 100 and the working costs are greater than 0."

As to what constitutes a complex ore there is also a general agreement, although it is apparent that a wide variety of ores can be included in the term. Generally speaking they contain sulphides of lead, zinc, iron or copper, with or without gold and silver, zinc being regarded as a characteristic constituent. Prof. George and others cite a wide variety of complex ores.

From the ore-dressing point of view Mr. Guess and Mr. Collins regard as complex, an ore containing several metals which have to be separated, and which are difficult to separate into marketable products; and which, we might add with Prof. Richards, "would have greatly increased value if separated." This implies, however, the *possibility* of such separation, even though it may not be done as satisfactorily or profitably as might be wished.

An extension of this classification covers similar ores of such physical characteristics as to *preclude the possibility of any separation of minerals* by ore-dressing devices. Hence, Mr. Bleecker and Mr. Johnson apparently regard ores as complex when they "cannot be treated by standard mechanical devices," or do not "admit of separation by mechanical methods." Mr. Bell cites an excellent example of this kind of complex ore.

This distinction between complex ores according to their amenability to mechanical methods of separation is more relative than exact, because as Mr. Croasdale points out, many of the ores now profitably treated by modern mechanical methods are subject to great losses; and sometimes the penalties on undesirable elements become prohibitive, as suggested by Mr. Ionides. The mere fact that ore-dressing methods are being used on some ores does not greatly affect their classification as complex; so that whether an ore can or cannot be treated mechanically, the problem remains of conserving resources, on the one hand, and making new ores available, on the other.

The smelter's point of view is reflected by Messrs. Austin and Traphagen. The former "might limit the definition to cover mixtures, in the treatment of which the extraction of one metal interferes with the recovery of another," and cites an ore containing zinc blende in addition to sulphides of lead and copper. Dr. Traphagen mentions the same fact and says that "our metallurgical processes save but a few metals and sacrifice others of value." Mr. Clevenger points out the flexibility of the smelting process and its ability to treat a wide variety of ores, but he recognizes the inevitable loss of some constituents, notably zinc.

2.—In the discussion on the skilful use of present methods (ore-dressing and smelting) versus the need of new processes, we find a tendency to support the former while acknowledging the latter. Here we come squarely up against the classification of complex ores into those which can and cannot be treated by mechanical processes.

Mr. Swart is quite certain that "by far the greater proportion of (complex) ore can be successfully (profitably) handled by mechanical methods," in which opinion Mr. Godbe concurs. Mr. Collins regards these ores as "amenable to (imperfect) separation by known methods or combination of methods." Prof. Richards thinks that "some of these ores would yield to present processes skilfully applied," and Mr. Thomson states that "such ores are in part amenable to treatment by present processes when properly conducted." These and other contributors recognize the need for more skilful operation, and the possibility of thereby improving results in ore-dressing; but an implied apology is made for the inherent limitations of the methods themselves.

Mr. Skinner, however, comes out squarely with a defense of ore-dressing methods and a strong criticism of the inefficient way in which they are used at many mills. "It is not a fact that poor methods make the losses high, but that the handling of ore-dressing methods is deplorable. * * * The poor quality of mill operation is no doubt responsible for the notion that there is a complex-ore problem." His comments on the operation of average mills are worthy of consideration. He recognizes, of course, that "it would be very foolish to say that some new procedure would not prove, in some cases, more desirable than the known methods," but it is his opinion that "with the possible exception of electric zinc smelting," and under conditions known to him, "complex ores should be treated by simple ore-dressing followed by the old procedures, as against any new chemical or other sort of scheme outlined to date."

On the other hand, and relating particularly to those ores which all agree are not amenable to mechanical processes, we find a demand for new methods. As Mr. Canby aptly says, "the amenability of these ores to present processes is not a question of operating skill." Dr. Traphagen acknowledges the possibility of improving present practice by more skilful operation, but does not see "as much room for progress in present methods, particularly mechanical processes, as in the development of new methods." Mr. Ionides calls attention to the combined losses in ore-dressing and smelting, and Mr. Croasdale suggests that "it is scarcely conceivable that the cost of treatment in a more direct and refined metallurgical process, whatever it may be, will exceed the cost plus the losses sustained by mechanical concentration and smelting."

3.—Whether there are many mines now idle which could produce a considerable tonnage of complex ore if suitable methods of treatment were known, is, we believe, one of the points on which popular opinion has been in error. The consensus of opinion of our contributors is that there are not many such mines. In other words, complete idleness in the mining of complex ores is likely to be due not so much to the real lack of treatment methods as to other economic causes. Mr. Swart sees the real problem in "small, scattered and dissimilar" ore-bodies, and attributes idleness to "such conditions as inaccessibility, heavy snow, poor transportation, high freight rates, high fuel, distance from market, lack of water, poor financing, bad management, ignorance, and improper mining and milling methods." This is an array of economic conditions outside the control of the metallurgist, and they suggest that the lack of a process is not the main reason for idleness of complex-ore mines.

As to the contrary opinion gained by Mr. Johnson from letters received as the result of "a two-month's campaign which had for its object the gaining of information as to the need of a process" for treating these ores, we question the value of such information. The average mine owner is a wonderful optimist regarding his property, and frequently obsessed with the idea that all his "mine" needs is a "process." Only those who have had experience can sympathize with Mr. Clevenger when he says that "it is no unusual thing for tremendous deposits * * * to shrink into nothing upon careful examination." Probably others have had the experience of Mr. Thomson who has examined many such alleged mines and found that "quantity of quality of ore was lacking in every case."

All this, however, does not preclude a genuine need for metallurgical improvement, even at mills now operating; for the method treatment, while profitable, may be yielding poor economic results. It is recognized also that there are some mines, although they are few, at which production is deferred awaiting metallurgical development.

4.—The object of our fourth query was to see whether any particular quality—physical, chemical or both—could be considered as characterizing complex ores. The replies are fairly in agreement, and a number of good points are brought out. From the ore-dressing point of view the following qualities may cause ore to be classified as complex: Intimate physical association of the constituent minerals; fineness of crystallization and friability of minerals; narrow margin between the specific gravities of sulphide constituents; similarity of specific gravity of mineral and gangue; chemical combination of different metals in a single mineral; similar action of minerals in flotation; and equivalent electrical and magnetic properties of minerals.

The economic phase is suggested by Mr. Collins, who says "it is mainly a matter of costs and market values"; and by Mr. Bleecker who observes that "an ore is not necessarily worth treating because the total values foot up to ten or twenty dollars per ton."

On the chemical side, those who seek to lay the cause of complexity at the door of a single constituent element are unanimous in selecting zinc as the offender. This metal has to bear the brunt of losses and penalties, and its recovery is one of the fundamental features of newly proposed processes. Prof. Richards speaks of zinc as "the worst stumbling block in the metallurgy of complex ores," and Mr. Johnson believes that "the great importance of a process that will *save the zinc* is manifest." Mr. Austin calls attention to the obstacles presented by zinc in the smelting process, and comments on its loss and that of accompanying metals.

5.—When we come to consider what processes may be regarded as possible solutions of the complex-ore problem, we find the greatest diversity of opinion. Excluding those opinions emanating from contributors personally interested in some process, we find two features among the balance: an expression of hope and confidence in the ultimate success of electric zinc smelting, and a favorable attitude toward hydrometallurgy.

Mr. Wiard alone anticipates that "mechanical processes will be more generally applied in the treatment of these ores." Others express more conservatively the thought that mechanical methods will hold their own for some time to come, because the newer proposals have not yet reached the stage of successful application and must await wide adoption until they have produced acceptable data from operation. It appears almost certain that in some cases preliminary mechanical concentration will have to accompany even hydro- or electrometallurgical schemes. Flotation is one of the newer mechanical methods in which some profess to see a hopeful solution in special cases; but even here, as Mr. Skinner points out, we are benefited only in the case of one-mineral separation. Where two or more sulphides are involved, flotation does not offer so much advantage.

In fact, in the whole realm of mechanical processes, it is not one, but two or more methods in combination to which we must look for economic ore-treatment. This "interminable mechanical grooming," as Mr. Croasdale puts it, is objectionable on the score of successive losses in each step; and its abandonment has been one of the chief incentives of those who advocate new processes to yield metals at the mine.

Mr. Ionides believes that "a solution of the problem along purely mechanical lines seems doubtful, and is inclined, with Mr. Bell, to think that "hydrometallurgical and chemical means will have to be employed." Others express similar sentiments. Mr. Clevenger is especially impressed with the possibilities of hydrometallurgy, which is coming to be of rapidly increasing importance and promises to be as useful in the recovery of non-ferrous metals as the cyanide process is for gold and silver. He sees in this line of development a possible solution of not only the complex-ore problem, but also the smelter-smoke problem. Obstacles to successful hydrometallurgy do not seem insurmountable to him in view of the remarkable work done at Cobalt in treating complex silver-cobalt-nickel-arsenic ores by cyanidation.

The objections to hydro- and electrometallurgy are voiced by Mr. Swart, who says that "plant cost on most of the proposed chemical and electrical methods is prohibitive for small mines," and by Mr. Skinner, who objects to "the handling of salts of high heats of formation in large volume of solution, calling for a high investment cost and demanding expensive chemicals."

Of the special processes proposed, Mr. Johnson is partial to electric smelting; Mr. Scibird and Mr. Ionides to some form of chlorination, and Mr. Bretherton to ammonia-carbon dioxide.

Speaking from the standpoint of a smelter, Mr. Austin is of the opinion that "it would be hazardous to suggest" along what line reduction methods will develop, but he believes it will be "not in the line of pyrometallurgy." It is interesting to compare this with the opinion expressed later by Mr. Clerc, whose experience leads him "to believe that there is an opportunity for the wider use of pyrometallurgical concentration" by modified forms of smelting or sintering. Mr. Clerc has in mind, as a particular case of the general problem, the lean oxidized ores of zinc and iron which, while not within the class of complex sulphides nevertheless present a problem of similar economic importance. These ores require some form of concentration in order to raise their zinc content to the grade required by zinc smelters. Not being amenable to any of the ordinary methods of enrichment, fire concentration is suggested. This would produce an impure zinc oxide for further reduction in a special furnace, and it is Mr. Clerc's suggestion to so modify current metallurgical practice as to enable the smelter to co-operate with the miner in utilizing this kind of ore.

6.—The general use of the microscope is commended in examining ores and products: to determine the fitness of the former for the proposed treatment and the efficiency of the process as indicated by the latter. Such examination will aid in locating trouble and may suggest the remedy. It will be specially valuable in the case of tailings, middlings and other products of wet and dry separation processes, and in observing changes in the character of the original ore supply. Several contributors to the symposium who are college professors state that they regularly train their students in this use of the microscope.

**General.**—The reader who is well posted on the subject of this symposium may feel that the tenor of the replies to our questions is about what he expected. At the same time it is worth while to have these opinions publicly expressed by competent observers, in order to crystallize the facts for the benefit of those less well informed. It is made clear that the problem is one of many phases. We cannot "use the same medicine for a number of widely different ills," as Mr. Haldane says. This is reason enough for considering the merits of all the various proposals and, above all, maintaining an open, unbiased mind. This is good advice to the promoter as well as the perspective user of new schemes. Panaceas are not favorably regarded by the well informed.

A useful hint to process inventors is given by Mr. Croasdale, who suggests that the best way to bring new processes to trial is to secure the support of operating companies that have the problem, the money and the willingness to spend it intelligently. "This can be readily done by appropriations set aside from earnings, which would virtually come from the properties themselves and not from the shareholders." Mr. Collins makes it plain, in this connection, that pioneer work in metallurgy is expensive, and that "the details of such processes (electric smelting or chlorination) should be worked out by large existing producers." The unfortunate tendency of small, inexperienced operators to try unproved processes is properly criticized by Mr. Godshall.

On the whole we believe that the symposium has given expression to many useful and constructive ideas, and has brought out strongly the spirit of willing co-operation which makes the ultimate solution of the problem seem far from hopeless. To all those who have contributed from their knowledge and experience, we express our thanks and hearty appreciation.

---

**The Titanium Alloy Manufacturing Company** announces that it has organized a Bronze Department for the manufacture of Titanium-Bronze Specialties under its various patents, and that Mr. Wm. M. Corse, formerly Works Manager of the Lumen Bearing Company, Buffalo, and lately General Manager of the Empire Smelting Company, Depew, N. Y., will be associated with the company as Manager of this department.

**A composition for treating boiler feed-water,** patented by Gilbert E. Bailey, of Los Angeles, Cal., consists of a mixture of graphitic iron and 1 to 4 per cent. zinc, the latter being added to the iron as it flows from a cupola. The alloy is turned into shavings or powdered.

**A new platinum alloy,** suitable for making scientific instruments, electrical contacts, and the like, has been patented by Exechiel Weintraub, of the General Electric Co. It consists of platinum and either tungsten or molybdenum, or the three together, platinum constituting about 20 parts of the whole. The alloy resists the action of air and has great mechanical strength.

**Transvaal Gold Production.**—The number of companies reporting to the Transvaal Chamber of Mines in March, 1914, was 60. The total quantity of ore milled during that period was 2,149,601 tons. There were 9662 stamps in operation, with an average duty of 8.82 tons per 24 hours. Tube mills in commission numbered 290. The yield for the month was 686,801 fine ounces gold.

# The Application of Physical Chemistry to Industrial Processes[*]

BY WALTER F. RITTMAN

The luxury of to-day is the necessity of to-morrow; likewise the theory of to-day is the practice of to-morrow. Gayley's process of drying air for a steel furnace, the various nitrogen-from-air processes, the contact process of manufacturing sulphuric acid, synthetic indigo, synthetic tanning materials—all were in the field of abstract theory but a few years ago. To-day they are practical realities. Similarly many of the theoretical principles and processes of to-day will in all probability be realities a few years hence.

The invasion of chemistry by physics and the production of what is known as physical chemistry, promises to be a most important basis for progress in the field of applied chemistry. Whereas physical chemistry is often looked upon as one of our most theoretical subjects, it will be found to be one of our most practical as well. Its principles are useful regardless of the materials involved in the reactions, whether copper, steel, soap, glass, cement, gas, textile, or any other chemical product. Physical chemistry is described as that branch of chemistry which has for its object the study of the laws governing chemical phenomena. When these laws and their application to a reaction or process are once understood it is a relatively easy matter to select the most favorable physical conditions. The task of the chemical engineer is to produce these most favorable working conditions in an apparatus which operates on an industrial scale. A further advantage of a knowledge of theoretical principles and perhaps one to be more frequently applied is the aid such knowledge gives in avoiding fantastic so-called improvements.

The chemical engineer rarely creates new products; he deals with processes and machinery which produce quantities economically. Obviously his problems often differ from those of the laboratory chemist. The fact that a reaction is slightly exothermic or endo-thermic is of secondary consequence in laboratory experiments, but in applied engineering this fact at once determines whether the reaction should be carried out in a cooled or in a heated apparatus. The amount of heat given off in a reaction, such as the hydrogenation of a vegetable oil, is of no serious consequence in laboratory experiments, but where tons are handled the accumulated heat is sufficient to ruin any process which does not provide for its disposal. Latent heat of fusion or of evaporation is not important in the laboratory where there is always an excess of heat or cold, but in many cases this heat of fusion or of evaporation becomes all important in its influence on the cost of an industrial operation. The cost of the heat absorbed by an endothermic reaction seldom concerns the laboratory chemist; but it is profit or loss to the chemical engineer. The percentage of yield, and the cost per unit, are the vital questions to the engineer; they are usually not vital to the laboratory chemist, however valuable and constructive his work may be.

It sometimes seems as if the inertia of years has limited the temperature imagination of many engineers and some chemists. Theoretical considerations might suggest the broad field which comprises the several thousand available degrees above the boiling point, as well as the 273 degrees below the freezing point of water. Likewise we are prone to overlook the great advantages which sometimes may be derived from the application of pressures greater or less than the one atmosphere which surrounds us and with which we are so familiar.

---

[*] A paper presented before the American Institute of Chemical Engineers, Troy, N. Y., June 17th, 1914.

Because of the numerous possibilities in the application of physical chemistry to industrial processes, I must greatly restrict myself in dealing with the subject. Some of the most interesting parts deal with equilibrium relationships, phase rule applications, radioactivity, energy considerations and electrolytic reactions. Excellent examples illustrating the successful application of each can be found, but to-day I shall deal in some detail only with the one mentioned first; i.e., equilibrium relationships.

I shall not attempt to deal with every branch of modern production which involves the equilibrium relations of physical chemistry, nor shall I attempt to advance speculations as to future applications of equilibrium relations in industry. The attempt will be confined to successful present-day applications, by way of examples. However familiar these processes may be, I hope that there will be at least something interesting, if not new, in pointing out that these familiar processes have a purely theoretical aspect. In fact, dealing with them historically indicates that they have all developed out of the most abstract theoretical reasoning into the practical machinery of economical production.

### Oxidation of Nitrogen From Air

It is known that at room temperature there is no perceptible union of the nitrogen and oxygen of air; it is known that at temperatures as high as 3000° C. only a partial union takes place; it is known that the amount which does unite is a function of the temperature. That is, at each temperature there is a definite percentage of nitric oxide formed, and equilibrium exists between the combined and uncombined constituents. In other words, the tendency of the uncombined constituents to combine at any particular temperature is exactly counterbalanced by the tendency of the combined constituents to separate at that temperature.

There is a true equilibrium. Experiment has proven that when air analyzing 79.1% $N_2$ and 20.9% $O_2$ is brought to equilibrium at 2400° C. the resultant mixture[1] analyzes 2.23% NO, 77.98% $N_2$ and 19.78% $O_2$, i.e., 1.115 per cent. of an atmosphere each of nitrogen and oxygen have disappeared in the formation of nitric oxide. Further let it be clear that this 2.23 per cent. of NO obtained at 2400° C. is not an accidental figure; it will always be the same when air of the above composition is brought to equilibrium at 2400° C.

This fact makes it possible to calculate the equilibrium constant for nitrogen, oxygen and nitric oxide at 2400° C.

$$N_2 + O_2 \leftrightarrow 2NO - 43{,}200 \text{ cal}$$

$$K_{2400°C} = \frac{p^2_{no}}{p_{n_2}\ p_{o_2}} = \frac{(0.0223)^2}{(0.7798)\ (0.1978)} = 0.0032$$

where $p$ represents the partial pressures of each of the three constituents, i.e., the part of the whole pressure exerted by each.

The constant K which joins these partial pressures has a definite numerical value for each definite temperature. The square of the partial pressure of NO, divided by the product of the partial pressure of $N_2$ multiplied by the partial pressure of $O_2$, for any mixture of these three constitutents in equilibrium at 2400° C. will be equal to 0.0032. Through the application of thermodynamic principles[2], it is possible to calculate the value of K′ for any other temperature from the above experimentally determined value of K for 2400° C.

From this value of K′ for any other temperature, as 3000° C. for example, it becomes a simple matter to calculate the yield of NO which will be obtained from any initial mixture of nitrogen and oxygen brought to equilibrium at that temperature. Percentages of $N_2$, $O_2$ and NO which satisfy the equilibrium relationship for any temperature will always be obtained when these constituents are brought to equilibrium at that temperature. Further, the reaction is reversible, and reaches the same results from either direction.

A number of values for equilibrium constants of this reaction at different temperatures have been calculated. From these values the percentage yield of NO from air have been calculated, and the calculations have been checked, as follows:[3]

TABLE I—COMPARISON OF CALCULATED AND OBSERVED VALUES OF EQUILIBRIUM CONSTANTS FOR THE $N_2 + O_2 = 2NO$ REACTION

| Temperature Degrees C. | NO (calculated from values of K) Per cent. | NO (observed) Per cent. |
|---|---|---|
| 1538 | 0.35 | 0.37 |
| 1604 | 0.43 | 0.42 |
| 1760 | 0.67 | 0.64 |
| 1922 | 0.98 | 0.97 |
| 2307 | 2.02 | 2.05 |
| 2402 | 2.35 | 2.23 |
| 3060 | 5.00 | .... |

It is observed that until 3000° C. is exceeded the yield of NO is below five per cent. The above clearly indicates how theoretical considerations show the limits of a reaction as well as the most favorable conditions for its industrial application. The oxidation-of-nitrogen process obviously is limited in practical application to localities where large quantities of cheap electric power are available.

### Contact Process of Manufacturing Sulphuric Acid

The contact process of manufacturing sulphuric acid, considered from the equilibrium view point, can be expressed by the equations:

$$SO_2 + \tfrac{1}{2}\, O_2 \leftrightarrow SO_3 + 22{,}600 \text{ cal}$$

$$K = \frac{p_{so_3}}{p_{so_2}\ p_{o_2}{}^{1/2}}$$

A few values[4] of K are given in Table II.

TABLE II—VALUES OF EQUILIBRIUM CONSTANTS AT DIFFERENT TEMPERATURES FOR THE $SO_2 + \tfrac{1}{2}\, O_2 \leftrightarrow SO_3$ REACTION

| Temperature Degrees C. | $K_p$ (experimental) |
|---|---|
| 400 | 580.0 (calculated) |
| 450 | 188.0 |
| 515 | 65.4 |
| 600 | 14.9 |
| 800 | 1.81 |
| 900 | 0.57 |

Upon calculating the maximum yields of $SO_3$ obtainable at the different temperatures from the various values of K, it is observed that the yield rapidly decreases as the temperature increases. This is in contrast to the nitric oxide illustration where the yield of NO from $N_2$ and $O_2$ increases with the temperature. As the temperature increases in the $SO_2 + O_2$ reaction the values of the equilibrium constants decrease rapidly. At temperatures below 400° C., however, the union of $SO_2$ and $O_2$ is too slow for an industrial process. At this temperature there is but a slight sacrifice of the percentage of $SO_2$ and $O_2$ combination.

[3] Nernst, Zeit, anorg. Chem., 1906, pp. 213-228. Zeit. f. Elek., 1906, p. 257, p. 529. Jellinek, Zeit. anorg. Chem., 1906, p. 229-276. Nernst-Finckh, Ibid, 1905, p. 116.

[4] Kuletsch, Berichte 1901, p. 4069. Bodlander u. Koppen, Z. f. Elek. 1903, p. 787. Bodenstein u. Pohl Ibid, 1905, p. 373.

Temperature, however, is not the only thing which influences a reaction of this nature. Without entering into a mathematical discussion of the influence of pressure, we can recall LeChatelier's principle: that pressure stimulates those reactions involving contraction, while vacuum encourages those reactions involving expansion.

Further, temperature and pressure do not complete the factors influencing chemical reactions where equilibriums are involved. The third and important factor is the relative concentration of the various reacting elements. The $SO_3$ reaction furnishes an excellent example showing the influence of the concentration of the combining reagents. Observing the mathematical expression for the equilibrium relationship,

$$K = \frac{p_{so_3}}{p_{so_2}\ p_{o_2}^{1/2}} \quad \text{or} \quad \frac{p_{so_3}}{p_{so_2}} = K\sqrt{p_{o_2}}$$

it becomes evident that the relative yield of $SO_3$, with respect to $SO_2$, increases as the partial pressure of oxygen increases, since the value of K for any given temperature does not change. This can best be observed by giving K the arbitrary value 200, and assigning to $O_2$ the partial pressures 0.25, 0.50, 1.00 and 2.00:

Then $\dfrac{SO_3}{SO_2} = 200 \times \sqrt{\text{partial pressure } O_2}$ and the ratios desired are given in Table III.

TABLE III—SHOWING EFFECT OF INCREASING THE CONCENTRATION OF ONE OF THE CONSTITUENTS IN AN EQUILIBRIUM

| Partial pressure of oxygen | Ratio of $SO_3$ to $SO_2$ |
|---|---|
| 0.25 | 100 |
| 0.50 | 141 |
| 1.00 | 200 |
| 2.00 | 282 |

This influence of an excess of oxygen is of practical value and is used in the commercial manufacture of $SO_3$.

### Synthesis of Ammonia from $H_2$ and $N_2$

Another illustration of the factors entering into chemical equilibriums involving temperature, pressure, and concentration is the Haber method of manufacturing ammonia from nitrogen and hydrogen[5]. The synthesis of ammonia from nitrogen and hydrogen depends upon the equilibrium represented by the expression:

$$\underset{\text{2 volumes}}{\tfrac{1}{2} N_2 + 3/2\, H_2} \leftrightarrow \underset{\text{1 volume}}{NH_3} + 13{,}000 \text{ cal}$$

$$K = \frac{p_{nh_3}}{p_{n_2}^{1/2}\ p_{h_2}^{3/2}}$$

A few investigated values for K are given[6] in Table IV.

TABLE IV—EQUILIBRIUM CONSTANTS FOR THE AMMONIA SYNTHESIS

| Temperature Degrees C. | K (experimental) | K (calculated) |
|---|---|---|
| 700 | ....... | 0.00068 |
| 800 | 0.00033 | 0.00036 |
| 1000 | 0.000148 | 0.000145 |

Haber[7] found that as the temperature rises above 500° C. the yield of $NH_3$ is low, while below 500° C. the rate of reaction is too slow. He eventually so perfected his experimental apparatus that his yields of $NH_3$ permitted him to calculate K from experimental data and compare the same with theoretical values. The close correspondence of the theoretical and actual values above indicate how experiment reinforced by theory will often show what can be expected in practice better than imperfect experimental results without theory. Without theory, in fact, Haber would never have known whether his experimental work was perfect, imperfect, or worthless.

In this ammonia reaction, equilibrium relations are such that when the reaction is practiced under atmospheric pressure the maximum yield is not sufficient to warrant industrial application. A yield of less than one quarter of one per cent. is of little more than scientific interest. Through the introduction of increased pressures, however, the contraction from two volumes to one volume is greatly favored and the process yielding twelve per cent. at once becomes of decided commercial interest. In the oxidation-of-nitrogen process, on the other hand, there is no change in the number of volumes, and pressure is without influence on the reaction. This pressure influence in connection with equilibrium relations is strikingly shown[7] in table V.

TABLE V—PERCENTAGE AMOUNT OF $NH_3$ IN THE EQUILIBRIUM OF THE REACTION $N_2 + 3H_2 = 2NH_3$

| Pressure in | Temperature Degrees C. | | | | |
|---|---|---|---|---|---|
| atmospheres | 550 | 650 | 750 | 850 | 950 |
| 1 | 0.0769 | 0.0321 | 0.0159 | 0.0089 | 0.0055 |
| 100 | 6.70 | 3.02 | 1.54 | 0.874 | 0.542 |
| 200 | 11.9 | 5.71 | 2,99 | 1.68 | 1.07 |

### Other Applications of Equilibrium Relations

The equilibrium relationship between reacting agents persists throughout all chemical phenomena. The relative amount of $CO_2$ to CO issuing from a furnace is primarily a function of temperature and pressure, and is influenced by the machine only insofar as the machine influences these variables. The equilibrium between $CO_2$ and CO in the presence of carbon for any temperature is reached regardless of whether one starts with CO or with $CO_2$, or with any mixture of the two.

$$CO_2 + C \leftrightarrow 2\, CO$$

$$K = \frac{p^2_{co}}{p_{co_2}}$$

TABLE VI[8]—EQUILIBRIUM RELATIONS BETWEEN CO AND $CO_2$ IN PRESENCE OF CARBON

| Temperature °C | Per cent by volume CO | $CO_2$ |
|---|---|---|
| 450 | 2 | 98 |
| 750 | 76 | 24 |
| 1050 | 99.6 | 0.4 |

Typical examples of this relationship are found in the kitchen stove, the factory boiler, the blast furnace, the gas machine or the open-hearth furnace. Doubling the size of the blast furnace changes the relative amounts of $CO_2$ and CO only so far as doubling the size of the furnace influences the temperatures in the various reacting zones. With increasing temperature the percentage of CO increases, with decreasing temperature the percentage of $CO_2$ increases.

In the blast furnace, for instance, not only are the CO and $CO_2$ in equilibrium, but the various oxides of iron are likewise in equilibrium with carbon, CO and $CO_2$, as well as with one another.

[7] F. Haber, *Jour. Soc. Chem. Ind.*, 1914, p. 49.

[8] J. Mellor, Modern Inorganic Chemistry, p. 713.

Consider the blast furnace reactions,

$$\begin{aligned} 2CO &\leftrightarrow C + CO_2 \\ Fe_2O_3 + CO &\leftrightarrow Fe_3O_4 + CO_2 \\ Fe_3O_4 + CO &\leftrightarrow FeO + CO_2 \\ FeO + CO &\leftrightarrow Fe + CO_2 \end{aligned}$$

from the equilibrium point of view; there is found to be a vital relationship between them. On first sight a series of equations of such a nature looks very complex, but on the application of equilibrium relationships, formulated by means of the phase rule diagram, it is found to be relatively simple and clear.

Experimental work[9] has been done on these relationships, from which it is possible to plot the diagram of equilibriums.

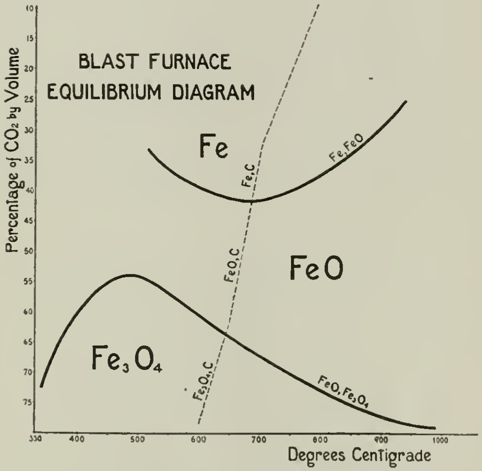

FIGURE I—BLAST FURNACE EQUILIBRIUM DIAGRAM, SHOWING RELATIONS BETWEEN C, CO, $CO_2$, Fe, FeO, AND $Fe_3O_4$

All of the reactions are reversible; their direction is entirely a function of temperature. From the diagram the fields of stability of Fe, FeO and $Fe_3O_4$ in the presence of CO and $CO_2$ for the temperatures shown can be observed. It can be observed, for example, that FeO at 650 deg. C. is not stable in the presence of more than 65% or less than 43% $CO_2$. It becomes evident that in the reduction of FeO to Fe a maximum of $CO_2$ in the flue gases is obtained when the reaction takes place at about 675 deg. C, and that this percentage of $CO_2$ decreases as the temperature increases. The diagram indicates that most of the reduction takes place in the cooler part of the furnace.

### Coefficient of Partition or Distribution

Equilibrium conditions also prevail in the more purely physical world as well as in chemistry. A solution which divides itself between two immiscible solvents will always be found in a definite concentration in both solvents, and there will always be a definite ratio between the concentration in each. This ratio is known as the partition or distribution coefficient.

I will cite first the laboratory example dealing with iodine, water and carbon disulphide. Iodine is slightly soluble in water and much more soluble in carbon disulphide, while water and carbon disulphide are practically insoluble in each other.

Suppose we have both water and carbon disulphide in one vessel and add some iodine. It has been observed from experiments that the concentration of iodine in the carbon disulphide is 588 times the concentration of iodine in water. In other words,

$$K_{iodine} = \frac{C_{cs_2}}{C_{h_2o}} = 588$$

In similar manner iodine divides itself between ether and water so that the concentration of iodine in the ether is 200 times the concentration of iodine in the water.

$$K_{iodine} = \frac{C_{ether}}{C_{water}} = 200$$

Similar examples can be found in the distribution of acetic acid between benzene and water, benzoic acid in benzene and water, succinic acid in ether and water, acetic acid in chloroform in water, saccharin in ether and water, acetanilid in ether and water, vanillin in ether and water, or acetanilid in chloroform and water.

This aspect of equilibrium is finding application in analytical chemistry, more especially in that branch dealing with alkaloids.[10] Through its application the haphazard washing out process in alkaloid work is replaced by one of mathematical precision.

Technical application can be found in Parke's process for extracting silver from lead. Silver is very much more soluble in zinc than in lead, whereas lead and zinc are only slightly soluble in each other. The lead containing silver is melted and thoroughly mixed with a small proportion of zinc. The zinc floats to the top, carrying with it in solution practically all of the silver, and on cooling solidifies while the lead is still molten. The zinc containing the silver is then skimmed off, and these two constituents separated.

Lack of time forbids the consideration of the equilibrium relationships existing in the ionization of acids, bases, and salts. Their application in analytical chemical methods is to-day a reality, their technical application promises much.

### Equilibrium Relations Are of General Application

The equilibrium or kinetic relationship is accepted and used by theoretical chemists, and is believed to prevail in practically all fields of chemistry. When considered in mathematical units it changes qualitative suggestion into quantitative information. Equilibriums deal with yields in terms of percentages or weights, they deal with temperature, pressure and concentration in numerical terms. When so applied, they are concrete and cease to be more theoretical than any other mathematical statement.

Equilibriums exist between reacting agents in solution; between reacting liquids; between liquids and vapors; solids and liquids; solids and gases; between gases which react chemically; between the concentrations of a solute divided between two immiscible solvents; in the ionization of acids, bases and salts, in hydrolysis and saponification; in fact in all the chemical and physical phenomena with which the chemist or the chemical engineer deals. The industrial development and application of physical chemistry, including this equilibrium principle, is only partially realized to-day; its further development and application seem to depend largely upon competition and necessity, and the stimulus they offer to the inventive faculties of chemical engineers as the leading specialists in this most promising field of our science.

## Recent Chemical and Metallurgical Patents

### Iron and Steel

**Method of Coating Iron with Zinc.**—In the manufacture of galvanized pipes for electric conduit purposes, Mr. **Peter McIlroy**, of Pittsburgh, Pa., has patented an improved process which he has assigned to the Enameled Metals Co., of Sharpsburgh, Pa. The pipe is successively immersed in alkali, acid and lime baths to prepare it for the coating of zinc. The electroplating is accomplished in two operations: first, by depositing a "strike" coat of copper and zinc in the proportion of 40 per cent copper and 60 per cent zinc; and second, by applying over this a coating of zinc. The inventor claims that this improved "strike" coat enables him to produce a coated pipe that will not be subject to corrosion. Pipe thus prepared is whiter and more uniform in appearance than other similarly coated pipe. (1,096,636, May 12, 1914.)

### Gold and Silver

**Continuous Slime Thickening Apparatus.**—In Fig. 1 is shown an apparatus patented by Mr. **John E. Rothwell**, of Butte, Mont., and assigned to the Colorado Iron Works Co., of Denver, Col. The object of the device is to continuously thicken a slime pulp, as in the cyanide process for gold and silver recovery, and to separate clear solution from the thickened pulp. The apparatus comprises a hollow cylinder 3, open top and bottom, supported in a cylindrical vessel with a conical bottom. An air lift is centrally disposed in the tank, having a receptacle at its upper end into which the lifted pulp is discharged, and from which it may be diverted through gates into a launder 12 or back into the inner cylinder. An overflow launder 9 surrounds the upper edge of the tank, to receive clear solution after it has been separated from the thickened pulp.

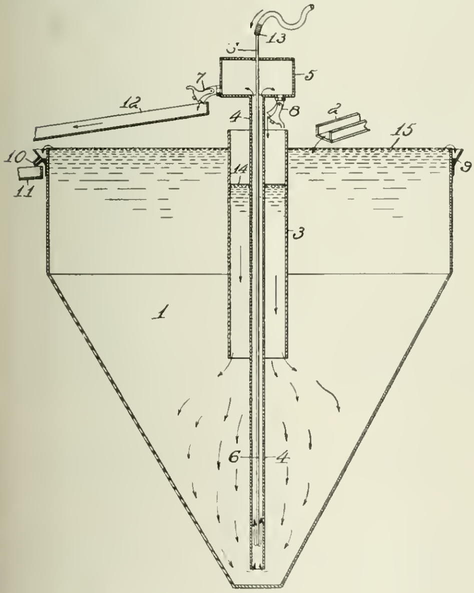

FIG. 1—CONTINUOUS SLIME THICKENER

In operation, a mixture of fine solids suspended in liquid is fed into the tank through the launder 2. The solids settle and the solution overflows. The settled solids accumulate in the cone and are elevated by the air lift. The latter is operated at a greater capacity than is necessary to supply the amount drawn off through launder 12, and this part returns to the cylinder 3. By this means the thickened pulp is kept in circulation and is prevented from accumulating in hardened masses on the conical side of the tank. A diaphragm pump may be used in place of the air lift. An application of the invention is to continuous decantation in the cyanide process, wherein thickened pulp of uniform density is withdrawn from the decantation vessels. (1,099,396, June 9, 1914.)

**Filter Leaf and Process of Dislodging Slime Cakes.**—A filter leaf from which the slime cake can be dislodged by means other than the application of reverse or internal fluid pressure, has been patented by Mr. **George W. Shepherd**, of New York City. The patent is assigned to the Butters Patent Vacuum Filter Co. In Fig. 2 is shown a side and end view of the leaf, and a plan of the water pipes used for dislodging the cake. The leaf consists of the usual pipe frame 5, perforated along the lower side and connected at 6 with a source of vacuum. A sack of filter fabric surrounds the frame and contains the customary slats 8, between which the two faces of fabric are stitched together as shown at 9. The upper edges of the fabric are held between the headers 16, bolted together at 15. Extending lengthwise of the frame, below the headers and outside the fabric are the pipes 1 and 2, slotted or perforated as at 10. These pipes join in a fitting 14 and are connected with a source of water under pressure. As shown by the dotted outline in the end view at the right, these water pipes are covered by the cake when it is formed on the fabric. After the cake has been formed and washed and is ready to be discharged, water is forced into the pipes 1 and 2 and directed by the slot or perforations between the cake and fabric, thereby causing the former to fall off. The feature of the patent is the admission of fluid beneath the surface of the cake. (1,096,132-3, May 12, 1914.)

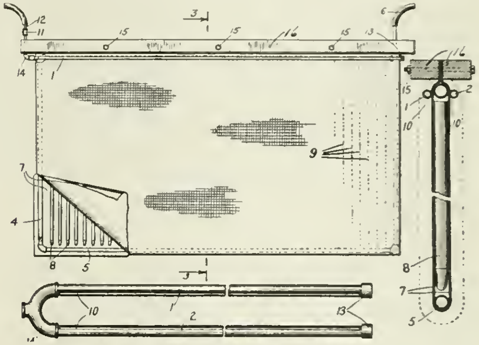

FIG. 2—FILTER LEAF

### Zinc, Lead and Copper

**Separation of Bismuth from Copper**—Mr. **William Thum**, superintendent of the lead refinery of the United States Metals Refining Co., Grasselli, Ind., has patented a process for the recovery of bismuth from the by-products of lead refining. The process is applicable also to bismuth-bearing refuse material, oxide slags from the treatment of bismuth-bearing copper, flue dust of copper furnaces and converters and from anode slime from electrolytic lead refining from which the antimony, arsenic and lead have been cupelled. Any material showing a concentration of bismuth in the presence of copper can be treated by the process, which consists in converting the copper into matte by fusing with an alkali sulphide, leaving the bismuth as metal which can be treated electrolytically.

The material containing bismuth and copper is first oxidized, crushed and mixed with an alkali sulphide, or preferably with an alkali sulphate and carbon. Salt cake and coke breeze are suitable materials. The mixture is smelted in a reverberatory furnace provided with a cupelling breast that can be scraped down to follow the level of the charge. The fluxing ingredients are added in amount equal to about two and one-half times that indicated by the theoretical requirements for reduction and conversion of metals and salts. When the mass is fused and in a perfectly liquid state it consists of three layers: on top is the soda slag, in the middle the copper matte, and beneath is the bismuth. Gold and silver, if present, are mainly in the bismuth, but some will be in the matte. The slag and matte are drawn successively, leaving the bismuth metal. If it now contains less than 1 per cent copper, it may be cast into anode bars and refined. If the copper exceeds 1 per cent, the metal is again converted to oxide by blowing air through it and the oxide slag is skimmed over the cupel breast. This material is then again crushed and smelted with fluxes as before. If the bismuth contains considerable gold and silver, this reoxidiation process may be performed for the purpose of recovering the precious metals, stopping the oxidation when but little bismuth remains and recovering the residue, which consists of a rich gold-silver-bismuth bullion. (1,098,854, June 2, 1914.)

### Rare Metals

**Extraction of Uranium, Vanadium and Radium from Ores.**—Among the numerous proposals made for treating radium-bearing ores is that of Mr. **J. H. Burfeind**, of Nucla, Col. He claims that the treatment of carnotite (uranium-vanadium-radium ore) with sulphurous acid will yield a solution of uranium and vanadium, and a precipitate of radium-bearing material. His method is to agitate ground ore and water with sulphur dioxide, whereby uranium and vanadium are dissolved, and barium and radium precipitated as a fine slime. By allowing the gangue to settle for a brief interval after agitation, he claims that the barium-radium precipitate remains suspended in the uranium-vanadium solution and can be decanted with it. By passing the liquid through a filter press the radium precipitate is retained and the solution clarified. The latter is then heated to drive off sulphur dioxide, whereupon the sulphites of uranium and vanadium are precipitated, recovered and subjected to any further treatment desired. The radium precipitate also is subject to further refining. (1,095,377, May 5, 1914.)

**Ductile Tungsten.**—A method for preparing bodies of tungsten, molybdenum and similar refractory metals which can be drawn, bent and otherwise worked, is patented by Messrs. **Paul Schwarzkopf** and **Siegfried Burgstaller**, of Berlin, Germany. The operation is performed in two steps and consists of a combined reducing and sintering process. Tungsten oxide in powdered form is compressed into rods, producing relatively strong and coherent pieces of metal oxide. These rods are then subject to a temperature of 1100 to 1150 C. in a stream of hydrogen, with the result that the material is sintered and partly reduced. The next step is to heat the rods by a current of electricity in an atmosphere of hydrogen at a temperature of 2600 to 2700° C. The resulting rods are ductile and can be bent into a ring at red heat. (1,096,464, May 12, 1914.)

### Ammonia

**Ammonia from Calcium Cyanamid.**—For the production of cyanamid first calcium carbide is made in an electric furnace; this is ground fine and charged into the cyanamid oven, where it is caused to react with nitrogen, forming calcium cyanamid, $CaCN_2$. This cyanamid carries about 60 per cent. calcium cyanamid, about 25 per cent. lime, 12 per cent. graphite, and other impurities in minor quantities, derived principally from the presence of foreign materials in the lime and the reducing agent used in the carbide furnace. If such cyanamid is treated with steam, at a high temperature, the calcium cyanamid is broken up with the evolution of ammonia, $CaCN_2 + 3H_2O = 2NH_3 + CaCO_3$. The ammonia is evolved as a gas and there is left behind in the treating apparatus a sludge consisting of calcium carbonate, calcium hydrate, graphite and impurities. On account of its physical condition this sludge could not be economically treated again in the carbide furnace in the past. This is made possible, however, by an invention of **Kenneth F. Cooper**, of the American Cyanamid Co., of Niagara Falls, Ont., Canada. If in preparing the cyanamid for treatment with steam a small quantity of an alkaline or alkali salt (1 to 2 per cent equivalent of $Na_2O$ in per cent of weight of cyanamid decomposed) is added, it affects in no way materially the evolution of ammonia, but when the resulting sludge is burnt in a rotary kiln or other calcination furnace, a porous clinker is produced of suitable size for carbide furnace charges. (1,100,539, June 16, 1914.)

### Caustic and Chlorine

**Sodium Chloride Electrolysis.**—Mr. **Herbert H. Dow**, of the Dow Chemical Company of Midland, Mich., patents a diaphragm cell for the production of caustic soda and chlorine from brine solutions. The carbon anode is enclosed in a dome which covers one-half of the cell and extends downward some distance below the normal level of the liquor. The chlorine gas accumulates within the dome from which it is withdrawn. The cathode is provided in the form of a horizontal wire mesh in the open portion of the cell. A horizontal diaphragm forms automatically below the cathode by the precipitation of the insoluble hydrates of the impurities in the solution. (Patent 621,908, March 28, 1899.) The solution containing the cathode above the diaphragm is always pure sodium chloride, while impure brine is used as anolyte. (1,100,290, June 16, 1914.)

## Synopsis of Chemical and Metallurgical Literature

### Gold and Silver

**Assaying for Gold and Platinum Metals.**—The assay of precious metals existing in black sand, concentrates and "battery chips" from South African mills has attracted the attention of chemists in that country, resulting in the publication of a number of papers on the subject. In our issue for November, 1913, page 652, we reviewed two methods bearing on the subject. In the *Journal* of the Chemical, Metallurgical and Mineralogical Society of South Africa, February, 1914, Mr. Andrew F. Crosse makes a further contribution to the subject, believing that it is important to ascertain to what extent platinum and allied metals are being lost to the producers by being sold as gold bullion. His method for gold, platinum and osmiridium is as follows:

Having obtained lead buttons from the ordinary crucible assay, they are cupeled with the addition of

2 to 4 mg. silver. This large quantity of silver is advisable when much iridium is present. Having obtained a bead of silver from the cupelation, proceed as follows: Melt some pure cyanide of potassium in a porcelain crucible over a Bunsen burner, having the crucible about half full. Add metallic cadmium to the amount of three times the weight of the silver bead to be treated, and when the cadmium is melted and can be plainly seen through the molten cyanide, drop in the silver bead. It quickly alloys with the cadmium, and the crucible is given a rotary motion to insure thorough mixing of the alloy. Pour the melt into a warm mold, recover the alloy by dissolving the cyanide in hot water and digest the metal in dilute $HNO_3$ (1:3). Cadmium and silver dissolve, leaving the other metals as a black powder. Filter, wash and burn the residue in a platinum dish at low temperature. Melt the residue with 10 g. acid potassium sulphate to dissolve rhodium and palladium if present. Digest the melt in warm water, filter and wash. The residue contains gold, platinum and osmiridium. Dissolve in aqua regia, obtaining gold and platinum in solution and osmiridium as a black residue, which is filtered, washed, calcined and weighed. The filtrate is evaporated twice to dryness in a porcelain dish, with addition of a few drops HCl each time. Dissolve in water and precipitate gold with $SO_2$. Filter and cupel the gold with lead. Precipitate platinum from the filtrate by acidifying with HCl and adding magnesium wire or ribbon. Filter, wash, calcine and weigh. The author states that he has made synthetical tests with gold and platinum and has obtained good results. In the discussion which followed the presentation of the paper, Prof. G. H. Stanley stated that he doubted if iridium is collected in the lead button in the ordinary crucible fusion. He believes that some of it goes into the slag, and that several re-assays of the slag may be necessary to collect all of it. He also stated that iridium is not easily filtered, even with the best papers. Mr. W. Cullen was of the opinion that the rarer precious metals existed in concentrates in sufficient quantity to make it worth while extracting them instead of allowing them to go out in gold bullion.

### Zinc and Copper

**Electrolysis of Fused Material Containing Zinc.**—A thesis by Mr. **Chun Hao Wang** presented for the degree of Ph.D. at Columbia University, contains an account of an experimental investigation carried out under the direction of Prof. E. F. Kern, on the freezing points of different zinc salt mixtures and the solubility of zinc sulphide and oxide in them. A longer review of this work is reserved for our next issue.

**Leaching with Dorr Classifiers at Butte & Duluth Mine.**—The use of modified Dorr classifiers in leaching oxidized copper ores is described by Mr. **C. S. Herzig** in *Bulletin* No. 116, Institute of Mineralogy and Metallurgy. Before adopting the present system the ore was treated by crushing to ½-in. and leaching for 48 hours in lead-lined vats with a 10 per cent sulphuric acid solution, following by a wash with water. The solution was precipitated by electrolysis or on iron. In order to improve extraction, experiments were made with Dorr classifiers in which wooden parts replaced metal that would come in contact with the acid solution. The first results were favorable, and the system finally adopted was as follows: The classifiers are 8 ft. wide and 30 ft. long, placed in series, the discharge of one falling into the next. The first four are for acid treatment and the last two for water washing. About 60 minutes' contact with acid is allowed. The ore is crushed to 10-mesh and is fed to the first classifier with solution from the first washing classifier. The overflowing slime passes to a vat beneath and is filtered through a bed of crushed ore. The coarse pulp progresses regularly through the line of classifiers. From the second, third and fourth machines, solution is drawn for precipitation by electrolysis. From the fifth the solution is used to mix with the original ore entering the first, and from the sixth the solution passes to precipitation on iron. Ten per cent sulphuric acid is used. The copper solution coming from the classifiers contains about 6 per cent acid and 4 to 5 per cent copper. Leaving the electrolytic plant, the solution contains about 8 per cent acid and 1½ to 2 per cent copper. Earthenware pumps have proved superior to lead-lined in handling the acid solution. Hickory, maple and glass teeth have been tried on the classifiers, but maple and hickory have proved best.

### Smelting

**Handling Flue Dust.**—The difficulty sometimes experienced in handling flue dust from blast furnaces prompts Mr. **Erle Huntley** to describe a simple method used for this purpose at the Hampden Cloncurry Copper Smelting Works, North Queensland. His paper appears in *Bulletin* No. 115, Institute of Mineralogy and Metallurgy. The furnace gases at this works are discharged into a collecting flue 9 ft. high and 7 ft. wide, and thence into a main settling flue 27 ft. high and 18 ft. wide. The increased area of this latter flue reduces the speed of the gas to about 240 ft. per minute. No baffle plates are used. The bottom of this flue is in the form of a trough, along which runs a ⅝-in. endless chain drawn by a sprocket wheel operated by a motor. The chain passes through the flue and returns along its top, being supported by pulleys. The chain travels at the rate of 40 ft. per minute, and is operated 6 hours per day. This suffices for the removal of about 12 tons flue dust, which is delivered into a collecting hopper in the bottom of the flue. In discusssing this paper (*Bulletin* No. 116) Mr. **T. C. Cloud** suggested that the attachment of discs to the chain would be more effective. No mention being made as to the method of closing the flue where the chain passed through its walls, Mr. **Cloud** suggested that if discs were used the chain might pass through tubes just about the diameter of the discs and long enough always to insure the presence of two discs in the tube, thus keeping the openings closed to the admission of outside air. Mr. **S. J. Speak** questioned whether dust losses by way of the stack could be avoided when the gas had a velocity of 240 ft. per minute, or 4 ft. per second, as it had been his experience that appreciable loss occurred at this velocity.

### Crushing and Grinding

**Kick's Law of Crushing.**—Mr. **S. J. Speak** makes a further contribution on the subject of crushing and grinding, giving in *Bulletin* No. 116, Institute of Mineralogy and Metallurgy, his views on the application of Kick's law to the measurement of energy consumed in crushing. Kick's law is stated by Stadler as follows: "The energy required for producing analygous changes of configuration of geometrically similar bodies of equal technological state varies as the volumes or weights of these bodies." Mr. Speak points out an important limitation to the correctness of this law, in that it assumes that the tenacity of a material is a constant quantity. This assumption is true for sizes appreciable by the naked eye, but does not hold good for fine sizes. He cites the enormous increase in tenacity in fine threads of spun glass and metallic wire, and shows that Kick's law becomes more and more inaccurate as sizes of rock or ore become finer. Another point of limitation is that ore is not a body of "equal technological state." It may contain vugs filled with soft, powdery material, or cracks filled with clay. The first fractures will take place along cleavages and weak places. Consequently the tenacity of a piece of such ore 4 in. in diameter will be much less than of a piece 1/10 in. in diameter. Further, much of the ore may be converted into slime without the expenditure of much energy. In general, the author comes to the following conclusions regarding the applicability of Kick's law, believing that they are borne out by actual experience.

1. It will tend to overestimate the energy consumed in coarse crushing.

2. It will tend to underestimate the energy consumed in grinding non-slimy sand to slime.

3. It will tend to overestimate the work done in making slime from such ores as contain slime as an original constituent.

**Graphic Record of Screen Analysis.**—In order to convey quickly to the mind the results of a screen analysis of crushed ore, Mr. S. J. Speak has shown in *Bulletin* No. 116, Institute of Mineralogy and Metallurgy, a method for graphically recording the results. Fig. 1 shows the graphic record of the figures given below:

| Screen Mesh | Aperture Inches | Percentage in Tube Mill Feed | Percentage in Tube Mill Discharge |
|---|---|---|---|
| + 12 | 0.03937 | 27.6 | ... |
| + 20 | 0.02480 | 15.7 | ... |
| + 30 | 0.01562 | 13.7 | 7.4 |
| + 50 | 0.00984 | 19.9 | 22.5 |
| + 80 | 0.00620 | 15.5 | 29.0 |
| + 120 | 0.00391 | 2.0 | 6.0 |
| + 200 | 0.00246 | 1.6 | 7.7 |
| — 200 | ...... | 4.0 | 27.4 |

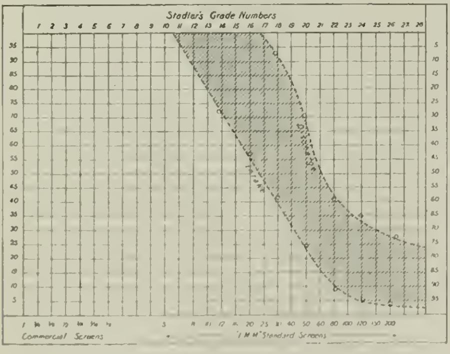

FIG. 1—GRAPHIC RECORD OF SCREEN ANALYSIS

Referring to Fig. 1, the left-hand lower portion of the diagram represents the energy already expended on the ore, and the right-hand upper corner shows the work remaining to be done to reduce the ore to the finest grade. The shaded portion represents the useful work done by the tube mill, which can be measured more readily and satisfactorily than by the mathematical method used by Stadler.

## An Economic Way to Handle Shipment of Long Iron Rods

The recent installation of a Shaw electric crane at the plant of the Bayonne Bolt & Nut Company of Bayonne, N. J., illustrates in a pretty manner how a difficult problem of handling material was solved by the application of a few small strands of wire.

The Bayonne Bolt & Nut Company receive quantities of bar stock-iron rods about twenty feet in length, and ranging in diameter from one-quarter inch upward. This raw material comes in gondola cars on the company's private switches.

The unloading and stacking of the rods by hand was, however, a slow process. The rods had to be lifted, one at a time, from the cars and carried to various parts of the yard. From the flexible and yielding nature of the material the "stocking" of a shipment was necessarily slow and, of course, expensive.

In seeking a better way to do the work an electric crane and magnet naturally suggested themselves, but the nature of the material to be handled again interposed an obstacle. With the rods lying loosely in the car a hoisting magnet could not pick up a clean load. Some rods would hang and swing. To obviate this, the expedient of having the consignors wire the rods together in bundles was adopted. With the rods in bundles it became possible to employ an electric crane and a magnet economically and the apparatus was installed by the Shaw Electric Crane Company. With the bar stock in bundles the magnet makes a clean lift not merely of one bundle, but of bundles up to its lifting capacity.

ELECTRIC CRANE FOR HANDLING IRON RODS

They are raised out of the car and piled practically at one operation. With the crane and magnet the company can now accomplish in a few minutes work which under the old method took a gang of freight handlers hours to do.

There is besides the saving in labor a gain in the speed of handling raw material. Furthermore, the use of the crane permits the piling of rods to a greater height than would have been economically possible by hand work.

## Filter Press Experience in a Cuban Sugar Plant

In our Vol. IX, page 381 (July, 1911), we noticed some interesting development work on filter presses carried out by Mr. John J. Berrigan, and in our Vol. XI, page 286 (May, 1913), we stated that the Berrigan filter press has been taken over by the Hy. R. Worthington Pump Company, of Harrison, N. J. The following report of the commercial operation of a Worthington filter press at Central Armonia, Bolondron, Cuba, should be of particular interest.

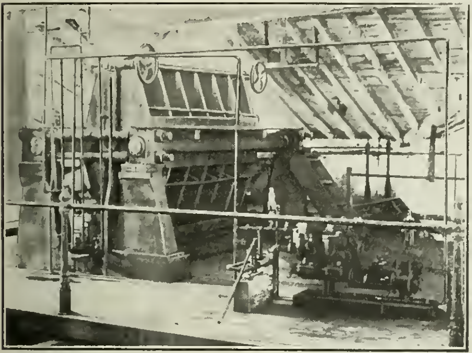
In actual continuous operation during the past crop for over a month at the Central Armonia for filtering cachaza, the Worthington filter press is stated to have shown the following advantages over the old-style frame presses in use in Cuban mills.

1. *Greater Efficiency.* A great saving of time is effected in the opening and closing of the press; in the dropping of the press cake and the placing of the filter

bags, as well as a great saving of labor expended. This permits of the press being idle but a very small percentage of the time.

The average capacity of the press may conservatively said to be at least 400 gal. of cachaza per hour. One press will do practically the work of four thirty-frame presses, rated at 1/3 m filtering surface per frame.

The filter bags can be used several times over without washing. On one test at the Central Armonia, the same set of bags was used continuously for fifty-six hours without washing.



WORTHINGTON FILTER PRESS IN CUBAN SUGAR PLANT

The simplicity of operation allows the employment of ordinary unskilled labor, there being no danger of breakage or of getting the press out of order.

2. *Economy in Operation.* Three men are sufficient to operate a battery of three presses which is sufficient to filter the cachaza resulting from a daily grind of 80,000 arrobas (1000 tons) of cane, including the washing of the bags, thus reducing from one-half to two-thirds the labor cost of operating the old-style frame presses.

3. *Saving in Material.* As but three bags are used in the filtering process a great saving is effected in filter cloth material used. Five sets of bags should be ample to make a crop, at a total cost of about $100 per press for material. Therefore, on the basis of a mill grinding 80,000 arrobas of cane every twenty-four hours and with three Worthington presses in use for filtering the cachaza, the total cost for filter cloth material should not be over $300 for the crop, as against a cost of from $1,000 up for filter cloths needed in operating the old-style frame presses.

There is very little tearing of the bags, which eliminates a considerable expense for repair of filter cloths.

4. *Better Results Obtained in Filtered Juice and Press Cake.* The juice is filtered perfectly, a brilliant liquor resulting, and entirely free from all small particles of fiber and other materials detrimental to elaboration.

The press cake is always well formed and can be removed from the bag very easily. The press cake shows from 10 per cent to 20 per cent less sucrose content than that shown in the cake resulting from the old-style frame presses under equal conditions.

5. *Economy for Repairs.* As there are no parts about the press than can be easily broken, the expense of replacing broken plates and frames is eliminated. The cost of upkeep on the press is practically negligible.

In Table I data are given as to the actual results obtained in operation of the Worthington filter press at the Central Armonia, during the crop just ended.

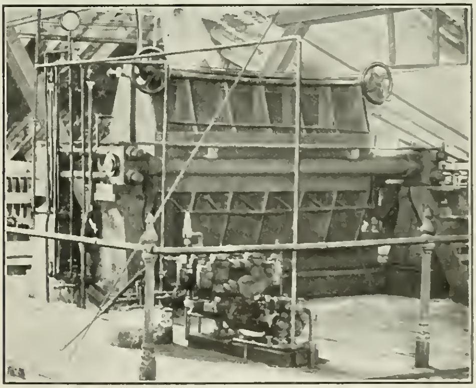
TABLE I—TESTS RUN AT CENTRAL ARMONIA WITH WORTHINGTON FILTER PRESS

| | 1 | 2 | 3 | 4 | 5 Av. |
|---|---|---|---|---|---|
| Minutes required to fill bags with cachaza | 3.5 | 2.5 | 3.0 | 2.0 | 2.75 |
| Minutes required to close press and make seal | 2.5 | 3.0 | 3.5 | 4.5 | 3.38 |
| Minutes required lowering press without pressure | 6.5 | 7.0 | 14.0 | 12.0 | 8.88 |
| Minutes required to close press under hydraulic pressure | 21.0 | 29.0 | 17.0 | 10.0 | 19.25 |
| Minutes required to raise press and drop bags with cake | 9.0 | 3.5 | 3.0 | 3.5 | 4.75 |
| Minutes required to put in empty bags | 4.0 | 4.0 | 6.0 | 6.5 | 5.12 |
| Total minutes required for complete operation of press | 46.5 | 49.0 | 46.5 | 38.5 | 45.13 |
| Gallons of cachaza per charge | 291 | 304 | 290 | 278 | 291 |
| Gallons cachaza filtered per hour (rate) | 375 | 372 | 374 | 433 | 388 |
| Degrees Brix of filtered juice | 9.75 | 14.4 | 10.7 | 13.8 | 12.16 |
| Percent Sucrose of filtered juice | 8.10 | 12.6 | 9.1 | 11.9 | 10.42 |
| Percent purity of filtered juice | 83.2 | 87.2 | 85.1 | 86.5 | 85.50 |
| Pounds of press cake | 184 | 192 | 168 | 172 | 179 |
| Percent Sucrose in press cake | 5.4 | 7.0 | 6.4 | 7.2 | 6.85 |
| Percent moisture in press cake | 58.2 | 58.4 | 57.8 | 59.3 | 58.42 |
| Thickness of cake in inches | | | | | ⅝ |

The above tests were conducted under circumstances somewhat unfavorable to obtaining the most advantageous results as to the maximum efficiency of the press. With an installation of the press in a manner to allow of time saving, in the filling of the bags with cachaza, dropping the bags with cake and putting in of empty bags, the time required for complete operation of the press could be reduced from the above figures.

The press in action had 300 ft. of filtering surface.

The comparison made in Table II of the Worthington filter press with one of the latest type cylinder presses in use in some sugar factories will prove of considerable interest.



WORTHINGTON FILTER PRESS IN CUBAN SUGAR PLANT

TABLE II

| | Worthington. Average | Late Type of Cylinder Press. Average |
|---|---|---|
| Total minutes required for complete operation of press | 45.13 | 160 |
| Gallons of cachaza per charge | 291 | 750 |
| Gallons of cachaza filtered per hour (rate) | 388 | 280 |
| Degrees brix of filtered juice | 12.16 | 14.5 |
| Percent sucrose of filtered juice | 10.42 | 11.1 |
| Percent purity of filtered juice | 85.50 | 76.6 |
| Percent sucrose in press cake | 6.85 | 8 |
| Percent moisture in press cake | 58.42 | 79.2 |
| Thickness of cake in inches | ⅝ | ⅝ |

## Electric Annealing Furnace for Brass and German Silver Ware

An interheating electric furnace for annealing brass and German silver flat ware blanks has just been installed in the plant of one of the best known makers of plated ware in this country, located at Niagara Falls, New York.

The furnace framework is made of steel shapes and plates, and is 15 ft. long, 8 ft. wide, 7 ft. 6 in. high. The doors are located at both ends of the furnace.

A mechanical pusher operated by compressed-air cylinders running over cast-iron idler sheaves operates the pusher mechanism located at the charging end of the furnace. The material under treatment is packed in steel pans 20 inches square which are forced through one after another, seven pans being in the furnace at one time. The pans passing through the furnace are supported by a hearth made of cast-iron grids 24 inches square, and are of special design, which prevents undue warping at furnace temperatures.

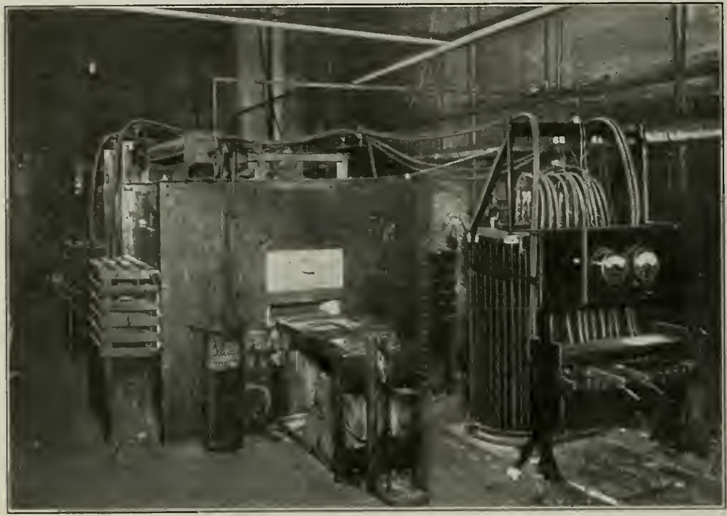


FIG. 1—FRONT END OF FURNACE AND ELECTRIC FURNACE

The pan coming out of the discharge end of the furnace is automatically dumped into a water-sealed discharge hood. The metal under treatment falls into a tank of either clear water or pickling solution, depending upon the cleanliness of the material before it is charged into the furnace. The pan itself is caught by two rails and held suspended above the trough and may be taken out from under the water sealed hood through the counter-balance swing door shown in Fig. 2.

The operation of the furnace is as follows:

A pan of flat ware is placed on the runway in front of the pusher—as shown in Fig. 1. The small hand lever shown near the top of the furnace frame in Fig. 1 is pushed upwards, which operates the air valve on the cylinder shown on the top of the furnace in the same figure. The first movement of the cylinder raises both the front and the rear doors to a sufficient height to admit the pans, which are 3 inches high.

At this point a stop on the cable holds the doors at this height and the pusher with the pan of fresh material starts into the furnace, pushing ahead of it the seven pans already in the furnace. At the moment the fresh pan is completely inside the furnace, the pan at the discharge end has been pushed clear of the furnace opening and door onto a dumping carriage. The weight of the pan striking the base of this carriage automatically tips the pan and it turns completely over, dumping the contents in a hopper, the lower end of which is submerged in the quenching tank. The pan, now upside down, is caught by two rails and held above the water and is taken out through the counter-balanced swing door shown in Fig. 2.

The material dumped into the quenching tanks falls into a perforated copper basket, which is lifted at intervals out of the quenching tank.

At the same time that the pan-dumping mechanism starts to tilt, the pusher carriage is pulled out of the charging end of the furnace by the counterbalanced door shown in Fig. 1, and immediately after the carriage clears the opening the two doors drop too, simultaneously. It will thus be seen with this furnace that the material is not exposed to the atmosphere at any time after entrance to the furnace until it is taken from the quenching tank cold. This entirely eliminates any possibility of oxidation at any stage during the heating or cooling, as the furnace itself has a reducing atmosphere at all times.

The electrical equipment consists of a special 200-kilovoltampere transformer, built by the Pittsburgh Transformer Company, and arranged with 12 voltage taps so connected to the special controller shown in Fig. 1. The switching mechanism is so connected with the transformer leads that a very fine regulation of the voltage, and hence the wattage, may be readily obtained. This switch is mounted on a switchboard frame and is located directly in front of the transformer, as shown in Fig. 1. The instruments on the switchboard panel consist of a Weston watt-meter and Foxboro pyrometer. The latter is connected up with a 48-inch couple placed directly over the pan about to be pushed out of the furnace, thus making it possible to know exactly at what temperature the material is drawn.

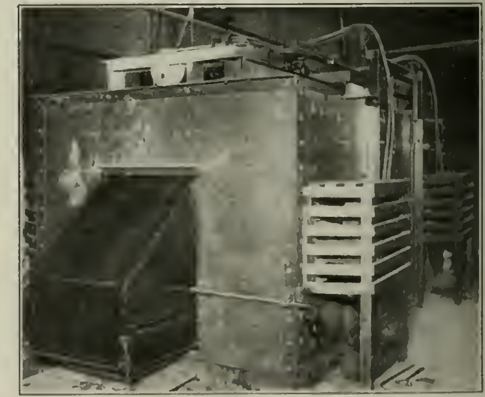

FIG. 2—DISCHARGE END OF FURNACE

The operation of this furnace has demonstrated clearly the superiority of continuous electric furnaces for the class of work handled, as the desired temperature may be reached with the utmost precision and without danger of overheating, and the ruling temperature at the end of the furnace is no higher than the temperature desired in the metal; and, further, the furnace atmosphere being always reducing and the material discharged from the furnace quenched from a sealed hood, eliminates the two most undesirable features usually found in fuel-fired furnaces; namely, lack of uniformity in temperature and oxidizing atmosphere.

This furnace was designed and installed by The Electric Furnace Company of America, Alliance, Ohio, who have recently received a duplicate order for a furnace of the same size and capacity for installation in the same plant.

## Personal

At the fiftieth anniversary of the Columbia School of Mines the honorary degree of Master of Science was conferred upon **John A. Church**, '67; **Wheaton B. Kunhardt**, '80; **Carl A. Meissner**, '80; **Arthur H. Elliott**, '81; **Francis B. Crocker**, '82; **J. Parke Channing**, '83; **Robert V. A. Norris**, '85; **Arthur S. Dwight**, '85; **Rudolph P. Miller**, '88; **Frederick W. Denton**, '89; **Karl E. Eilers**, '89; and **Gano Dunn**, '91; while the degree of Master of Arts was conferred upon **Henry F. Hornbostel**, '91 and **Goodhue Livingston**, '92.

Oberbergrat Professor Dr. **F. Kolbeck**, rector of the Bergakademie of Freiberg, Germany, was the official representative of Freiberg at the Columbia School of Mines celebration. He used the next few weeks for various trips to the Canadian cobalt district, Washington, D. C., the Franklin Furnace zinc mine, the Chrome (N. J.) copper refinery, etc. Before sailing for Europe he was the guest of honor at a dinner given by the Old Freibergers in America.

Dr. **Joseph W. Richards** has sailed for a professional and pleasure trip to Norway.

Professor **Hans Goldschmidt** of Essen-Ruhr, Germany, president of the German Bunsen Society and widely known as the inventor of the aluminothermic process and of electrolytic detinning, and Professor **Paul Askenasy** of the Institute of Technology of Karlsruhe, editor of the *Zeitschrift für Electrochemie*, were the guests of honor at an informal dinner given on June 8th at the Chemists' Club by the New York Section of the American Electrochemical Society. Dr. C. G. Fink, chairman of the section, presided and speeches were made by Dr. Baekeland, Dr. Goldschmidt, Dr. Askenasy, Dr. J. W. Richards, Dr. Alexander Smith, and Dr. C. F. Chandler.

Dr. **A. S. McAllister**, editor of *Electrical World*, has been elected president of the Illuminating Engineering Society.

Mr. **Charles F. Rand**, President of The Spanish-American Iron Company, Past President of American Institute of Mining Engineers, has been made a member of the Order of Isabella Catolica and decorated by the King of Spain with the Grand Cross of a Knight Commander.

Mr. **F. E. Pierce** has terminated his connection with The New Jersey Zinc Co. in whose employ he has served for over fifteen years in various capacities, for the latter part as chief engineer, and has opened an office to engage in consulting work in civil and metallurgical engineering at 35 Nassau street, New York City.

Mr. **H. W. Hardinge**, president of the Hardinge Conical Mill Company, has left New York for a combined business and professional trip which will include the Cobalt, Porcupine and British Columbia districts of Canada and Alaska, as well as the Western mining states. He will return in the second week of August.

Dr. **Richard Amberg** severed last January his connection with the Crucible Steel Company of America, where he was in charge of their new electric Heroult furnace, in order to accept the position of assistant manager of the Eisen-Industrie Menden-Schwerte, Germany.

## Digest of Electrochemical in U. S. Patents

PRIOR TO 1903.

*Arranged according to subject-matter and in choronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

*Electroplating* (Continued)

349,535, September 21, 1886, Andreas Söhner, of Carlsruhe, Baden, Germany.

Relates to a process of renovating gold and silver lace trimmings, real or imitation, and consists, first, in dissecting the trimmings into their several parts, such as metal, and metal-coated fabrics, cleaning the parts by subjecting to the action of steam to soften and remove greasy and other impurities, then subjecting the articles to solutions of soda and Panama bark, to remove further traces of grease, etc., then to a solution containing hydrochloric acid to neutralize and remove the alkali, then to a brushing with tartaric powder, then to the action of a silvering or gilding bath, and then to a final polishing.

360,517, April 5, 1887, James E. Emley, of Weatherford, Tex., assignor to W. J. Carson and T. D. Lewis, both of same place.

Relates to apparatus for recutting files, and consists in connecting a file to one terminal of a source of current, a carbon plate to the other, and immersing the file and carbon in an electrolyte, such as sulfuric or other acid, or caustic potash, or salt water. A plurality of files may be so treated at once by connecting each file between a pair of carbon plates.

The patent does not state whether the file is to be connected as anode or cathode.

362,257, May 3, 1887, William L. Dudley, of Covington, Ky., assignor to the American Iridium Company, of Cincinnati, Ohio.

Relates to electrodepositing iridium. An electrolyte of either the double chloride of iridium and sodium, or the double chloride of iridium and ammonium is used, containing about two ounces of metal and about one-half ounce of free sulfuric acid to the gallon of solution. From both of these solutions a thick, bright and reguline deposit is obtained, using as anode either a plate of iridium or of phosphide of iridium, the latter made by the process described in patent 240,216, dated May 10, 1881. During the plating operation it is necessary to avoid a current of too great intensity, which causes a dark powdery deposit; alkaline solutions should also be avoided.

367,731, August 2, 1887, William Arthur Thoms, of London, County of Middlesex, England, assignor to the Bright Platinum Plating Company (Ltd.), of same place.

Relates to an electrolyte for electrodepositing platinum, from which a bright white deposit of a fine, close reguline nature is said to be obtained. The proportions of the electrolyte may be varied, but the following are said to give good results: One ounce of chloride of platinum, twenty ounces of phosphate of soda, four ounces of phosphate of ammonia, and one ounce of chloride of sodium, all dissolved in water and diluted to a gallon of solution. A strong current of electricity should be employed—states a current of twelve amperes at ten volts; fresh platinum solution and chloride of sodium should be added to keep up the original strength.

429,386, June 3, 1890, Myron W. Parrish, of Detroit, Mich., assignor to the Graphite Electric Company, of same place, and John Hutchinson, of Jackson, Mich.

Relates to separating impurities from native graphite, and consists in connecting pieces of graphite, before crushing, as an electrode and short-circuiting in an electrolyte of sodium chloride with an electrode of zinc. The impurity said to be generally present is iron, although other metals may be present.

434,884, August 19, 1890, Charles C. Peters, of Springfield, Ohio, assignor of two-thirds to John V. B. Hoyle, and Charles W. Wadsworth, both of same place.

Relates to recutting files by electrolysis. The files are connected as anodes, in parallel, using carbon, etc., as cathode. The electrolyte preferred is not stated, but should have the properties of normally feeble and slow action upon the iron or steel of the file, but which will become rapid and caustic under the influence of an electric current.

437,648, September 30, 1890, Myer Hecht, of New York, N. Y.

Relates to ornamenting wood, ivory, or other nonmetallic surfaces, such as umbrella handles, workboxes, etc., by suitably engraving or carving figures thereon, as by channeling, and undercutting the side walls at such points as are essential to hold the metal. The engraved or channeled portions are now treated with plumbago, iron fillings, etc., in order that metal may be electrodeposited therein. When completed, the deposited metal is ground smooth and then electroplated with the desired finishing metal.

448,144, March 10, 1891, Augustin Personne de Sennevoy, of Paris, France.

Relates to recutting files, rasps, etc., and also engravings on steel, copper, zinc or other metals, and to the re-etching of steel and copper plates, and to the renovation of damaskened articles. It consists in making the file, etc., the anode of a battery and short-circuiting with a carbon cathode in an electrolyte of one hundred volumes of water, six volumes of nitric acid and three volumes of sulfuric acid.

## Book Reviews

**The Steel Foundry.** By **John Howe Hall.** Octavo (15 x 23 cm.), 271 pages, 37 illustrations; price $3.00. New York: McGraw-Hill Book Company, Inc.

The book is written by an engineer thoroughly competent to write on the chemistry, metallurgy and engineering involved. It is eminently practical, in that it keeps the dollar mark thoroughly in evidence in the descriptions and discussions. A long chapter on general considerations is very interesting reading, as it summarizes and compares in a clear and convincing manner the advantages and disadvantages of each method of making steel for foundry purposes, including detailed analyses of costs. A very strong case is made out for electric furnace steel, which it is predicted will entirely replace crucible steel; the thermal efficiencies of electric furnaces, however, negative the statement that they are less economical of electric power than other furnaces are of fuel energy—the reverse is the case. Among the raw materials we note the omission of the soft iron sponge which is being made so cheaply and extensively in Sweden; and in the open-hearth furnace chapter no allusion is made to the combined producer and furnace so successfully used in Europe.

However, where there is so much that is valuable and good, and also original, it is perhaps captious to note these few defects. Perhaps still more unimportant are the frequent omission of the zero before a decimal number (e. g., .95 instead of 0.95), the use of such expressions as "15 per cent of manganese" for "15 per cent manganese," and some uncertainties of expression which come direct from the foundry. The work as a whole is worthy of hearty endorsement; it will be of great service to all engaged in making steel castings.

* * *

**Engineers' Hand-Book of tables, charts and data on the application of centrifugal fans and fan system** apparatus, including engines and motors, air washers, hot blast heaters and systems of air distribution. Published by The Buffalo Forge Company, Buffalo, N. Y. Edited by **Willis H. Carrier**, First Edition (1914), 581 pages. Price $3.00. Buffalo, N. Y. The Buffalo Forge Co.

This is in more than one respect a remarkable book. It is the first complete and reliable treatise on fans and their standard applications to various industrial requirements. It is intended to be used as a guide in the selection and appliction of fans, heaters and kindred apparatus, and an effort has been made so to standardize the rules and data given that they may be used with any standard make of equipment. A technical reference book of this kind is rarely prepared by a manufacturing company; that the Buffalo Forge Company has succeeded in bringing out a volume of so much technical value and absolutely free from talkative self-advertising, is a credit to its engineering staff and a fine indirect advertisement for the company itself.

The amount of information contained in this little handy volume which can be conveniently carried in the pocket is enormous. This was made possible by utmost conciseness in the text and by giving most of the technical information in the universal short-hand system of engineers, that is, in form of diagrams, tables and formulas.

In the first chapter (35 pages) data on the properties of air are collected (weight of air; specific heat of air; relation of velocity to pressure; effects of temperature, humidity and barometric pressure on the properties of air; relation of dry-bulb, wet-bulb and dew-point temperatures; sensible, latent and total heat; psychometric charts and tables).

The second chapter (65 pages) deals with the applications of fans (heating; ventilating; air washing, cooling, humidifying, drying, mechanical draft; exhaust systems; miscellaneous applications).

The third chapter on "air ducts" gives detailed information on the design of various duct or conduit systems used for the conveying of air. The data on pressure losses and friction in piping and elbows are based on actual tests, many of which were specially made for this book.

The subject of proper proportions of piping in different systems, as well as the proper velocity of air, is also completely covered.

In part IV (356 pages) on "apparatus" the products of the Buffalo Forge Co. and the Carrier Air Conditioning Co. are, of course, primarily covered. Since the essential elements in most installations, using fans, are the fan, heater ducts or piping system, and some form of motive power for driving the fan, this section gives complete data relative to the performance and dimensions of fans, heaters and engines, together with detailed directions for carrying out fan tests.

Data on the performance and dimension of cast iron heaters are also given.

An appendix gives specifications and various reference tables for engineers.

The editor and publisher must be sincerely congratulated.

## The Atomic Weight of Gold

At the recent Leipzig convention of the German Bunsen Society, Dr. Krey in his speech of welcome on behalf of the German Chemical Society made the characteristic remark that not so long ago the older generation of orthodox chemists used to look at physical chemistry with feelings very much like those with which we (or some of us) view the art works of futurists and cubists. It is true this sentiment has changed, but if orthodox chemists were present at the Leipzig meeting, we are sure they must have been shocked by the papers by Dr. K. Fajans and Dr. O. Hönigschmid, who spoke of an indefiniteness of atomic weights and backed it up by the example of lead. And now they have been confirmed by so eminent and conservative an authority as Prof. Theodore W. Richards, of Harvard, who together with Max E. Lembert has determined the equivalent weights of sixteen samples of lead chloride obtained from different sources. "The result is amazing. Evidently, then, the chemical equivalents of these different specimens are markedly different from one another." Lead of radioactive origin has a lower atomic weight than common lead. And yet all the different specimens are chemically identical according to the most refined Harvard methods (we apologize to every Harvard man for this tautology). They are even identical according to spectroscopic analysis. They only differ in radioactive properties, and—in atomic weights. But what does it prove? That atomic weights are no longer constants of nature? Hardly, but it suggests that in lead there may be some admixture of very remarkable properties. What is it? Here is a wonderful opportunity for experimental research.

## Raw Material for Steel Production

A striking feature of the statistics of steel production in the United States in 1913, just issued by the Bureau of Statistics of the Institute, is that they show an increase in the output of ingots and castings of only 49,571 tons, or one-sixth of one per cent, over the preceding year, whereas pig iron production increased 1,239,215 tons, or 4.2 per cent. It is impossible to account for this divergence by inferring that stocks of pig iron increased during 1913. Analysis indicates clearly that the divergence was largely due to there being a higher proportion of basic pig iron to basic open-hearth steel in 1913 than in 1912, and this fact suggests a very interesting trend. The production statistics are as follows:

| | 1912 | 1913 |
|---|---|---|
| Pig iron in gross tons.... | 29,726,937 | 30,966,152 |
| Steel ingots and castings.. | 31,251,303 | 31,300,874 |

The production of foundry and mill grades, including foundry, malleable and forge iron, etc., increased from 6,423,312 tons to 6,605,366 tons, or 182,024 tons, 2.8 per cent, quite in keeping with the increase in pig iron as a whole. The production of Bessemer and low-phosphorus iron decreased from 11,664,015 tons to 11,593,385 tons, or 70,630 tons, while the production of Bessemer and acid open-hearth steel, almost the sole outlet for Bessemer and low-phosphorus pig iron, decreased from 11,467,122 tons to 10,801,011 tons, or 666,111 tons. The excess of pig iron over steel in 1913 was 7.3 per cent, which is only a trifle above the average; the excess in 1912, on the other hand, was below the normal, being only 1.7 per cent. It will be recognized that these percentages do not represent the loss in converting Bessemer pig iron into Bessemer steel ingots. There are other factors, the consumption of Bessemer pig iron in foundry operations, which is, however, quite limited, and, on the other hand, the use of scrap in acid open-hearth steel practice.

Comparing the production of basic pig iron with the production of basic open-hearth steel ingots and castings shows that in 1912 the proportion of pig iron to steel was a trifle over 58 per cent, while in 1913 it was nearly 62 per cent. This proportion is always suggestive of the quantity of scrap, chiefly new scrap, used in the basic open-hearth furnace in conjunction with pig iron, and we give below the proportions for each year since the statistics were first gathered. The statement begins with 1896, when the output was only 336,403 tons of basic pig iron and 776,256 tons of basic open-hearth steel, and ends with 1913, when the output was 12,536,693 tons of basic pig iron and 20,344,626 tons of basic open-hearth steel.

PROPORTIONS OF BASIC PIG IRON TO BASIC OPEN-HEARTH STEEL INGOTS AND CASTINGS, PER CENT

| | | | |
|---|---|---|---|
| 1896, | 43.3 | 1905, | 52.5 |
| 1897, | 52.7 | 1906, | 52.0 |
| 1898, | 50.1 | 1907, | 52.4 |
| 1899, | 47.4 | 1908, | 57.1 |
| 1900, | 42.1 | 1909, | 61.5 |
| 1901, | 40.0 | 1910, | 59.5 |
| 1902, | 45.2 | 1911, | 58.0 |
| 1903, | 43.0 | 1912, | 58.1 |
| 1904, | 48.5 | 1913, | 61.6 |

Minor variations in the percentage from one year to another may possibly be due to fluctuations in the volume of stocks, but these stocks are never particularly large, and the table shows conclusively a definite and important trend. In the earliest years the industry had not found its gait, and although there was doubtless much scrap available the largest proportion was not used. The maximum employment of scrap appears to have been in 1901, when the pig iron production was only 40 per cent of the steel production. For four years ending with 1903 the proportion of pig iron averaged 42.6 per cent, the proportion rising rapidly thereafter until 61.5 per cent was reached in 1909, and then with slightly lower percentages for three years a new high point of 61.6 per cent was reached in 1913.

The decrease in the relative consumption of scrap is not to be attributed to a failure in the supply of old material. Doubtless the outcome of old material increases from year to year, with more or less reference to the fact that ten, fifteen or twenty years ago, whenever it was that the present old material was new material, just put into use, the production and consumption of steel was increasing at a rapid rate.

Old material, however, does not furnish the chief supply of scrap for the open-hearth steel furnace, for the production of new scrap, including casting pit scrap, scrap produced by cropping in rolling, the shearing of plates and the fabrication of various steel mill products into final form, is much larger than the outcome of old material. The Bessemer steel process does not use its own scrap, and has not done so to any extent since the advent of the basic open-hearth furnace. The Bessemer steel industry, however, is decadent.

It does not follow that there has been in all plants an equal decrease in the proportion of scrap charged. The proportions have for years varied widely in different classes of plants. Those which use the least scrap, scarcely any, are, of course, the duplex works, partially treating the molten iron in the converter and finishing it in the basic open-hearth furnace. Statistics of dupex steel are available only for 1912 and 1913, the production being respectively 1,438,654 tons and 2,210,718 tons. Assuming for the computation that these duplex works used an equal tonnage of basic pig iron, it develops that the remainder of the industry used 54.8 per cent of pig iron in 1912 and 56.9 per cent in 1913. If one were able to segregate further and allow for the operation of Talbot furnaces, the proportion of pig iron would be found to be further reduced, but there is little doubt that the figures would show an increase in 1913 over 1912.

It is easy to foresee that as the industry grows in future and the basic open-hearth preponderates still more greatly over the Bessemer there will be a continued increase in the use of what may be called the non-scrap processes, and an increase in the proportion of pig iron used at the works which practice the regular pig and scrap process. The day of the blast furnace is not over, and it is even a question whether there is to-day sufficient blast furnace capacity at steel works to supply pig iron for full operation of the basic open-hearth capacity, increased as it has been so largely in the past few years.

### Arms and the Man

The past is effete and from us. The present is here and of us. The future is to come and for us. The past is valuable only as it teaches. The present is valuable only as we act. The future is good in that we can see. The three simple words, see, think, and act are part of a man's character, and how well one "sees, thinks and acts" distinguishes a man from a "mutt." Now coming from the past we find the adjectives noble, knightly, chivalrous that today possess the connotation of romance and give a glorious sheen to our thoughts. There is little of much greater value, nothing much more soul-satisfying, than the glory that comes from the day when knighthood was in flower.

How did these words acquire so much of beauty and of poetry and of spiritual grace, and how did knights rise to an honorable position? How did Chevalier Bayard "sans peur et sans rapproche" reach the ideal position? The reason we think can be found in progress of metallurgy and the reactance of metallurgy on esthetic and moral values is seen once again.

Brushing aside all verbiage and proceeding directly to our theme, we find that the man from prehistoric cave-man, seen incarnate today in a literary fashion in Jack London, has ever tried to get perfect weapons of offense and defense. This procedure was started in history by an eminent metallurgist bearing initials T. C. and went along under sign of the Hephaistos to the days of Colt, Krupp, and Maxim. It was by metallurgical reactions and by metallurgical endeavor that the suit of mail of Milan and the Toledo blade became perfect till at last even the feet were covered with protectors called "sollerets."

The perfection of armor was attained in the 15th century and was of such a degree that the shield was discarded as useless and the armored knight who was strong to mount his horse and move his muscles could not be wounded at all. The process was a gradual evolution, and had, long before that time in 1000 A.D. reached a temporary ultimate as is marked by the Battle of Hastings, where Norman knights conquered the Saxon warriors because they were better armed. Probably for six or seven centuries the man who had armor and was strong enough to carry it successfully was the first-class fighting man who dominated things so far as his power could carry. Finally, in the Battle of Crecy, which marked the introduction of gunpowder as a practical military agent, the kibosh was put on the knights and a new order of social affairs was started.

Let us analyze carefully these social changes—we had almost said economic changes, but all we had described happened before the days of Adam Smith. In feudal times a suit of armor was a valuable possession and constituted capital for its owner. But it weighed as much as 150 pounds and there were only a few men who were strong enough to carry such a weight and fight effectively. It was the exceptionally robust and tough man who became a knight. But provided he reached such a point in physical stamina that he could carry the armor and have surplus strength to use in offense, he was invincible against the man who did not possess armor or was not strong enough to fight in it. Given a man who reached a certain point in his physical make-up, he became all powerful. Below that point a man was defenseless because he was too slow.

For the men of the lower degree of fighting quality the only safety was in flight, and once caught whence he could not flee, he was lost and became a social by-product.

Such is in crude and bold outline the "Ursache" of knighthood. The knight was the exceptional man who was strong enough to carry armor and who, therefore, became militarily far stronger. A knight in armor could defeat in open fight, "ceteris paribus," 30 other men without armor.

Now with such objective conditions we might surmise that subjective conditions would be bad, that cruelty would be synonymous with bravery, that bad faith and treachery would constitute success, and that the weak would be pillaged by the strong to extermination. It would seem that the wolf and the shark would have assumed human form by a practical form of transmigration of souls.

What actually happened was quite the reverse. While injustice and rapine did exist, they decreased rather than increased. Loyalty, fealty, honor and self-sacrifice were in the knights' code given as the ultimate spiritual values. Women were placed in an idealized state and the flavor of chivalry pervaded life. The strong protected the weak and the weak repaid the strong by faithful service. In short, the power of association prevailed over the power of dissociation in a period when the "a priori" philosopher would have said that it was a question of how long before the "dog-eat-dog" method would have exterminated mankind. But while there was much of badness, badness did not increase, but rather goodness. Humanity energized joyfully in the days of old when knights were bold and ladies were fair. This is seen in the beautiful legends and stories of Arthur and the Troubadors. The novels of Scott and Dumas are true to the life of the feudal times. It was undeniably a time when moral values and spiritual values grew in beauty and strength.

With such cogitations and with such reflections in mind, we are struck with a certain analogy that today obtains in the world. The weapons that metallurgical science has forged today are commercial weapons of offense and defense, new processes to fight with, new thoughts to think with—science to materialize and to practicalize. But these weapons are so heavy that only the exceptional man can wield them. The thoughts of modern science are of commercial value, but it needs a thinker to absorb them. Those of lesser mentality who try, fail because of the nervous worry induced. Their powers are not strong enough and so they must sink to a subordinate position just as many men, weak muscularly, became in olden times archers, esquires or men-at-arms. We can see evidences of the inception of a process similar to the process that developed feudalism and chivalry. It may be undemocratic to foresee a triumph of aristocracy, but the future aristocracy will be founded on spiritual values and so an enduring one. The efficient man is vastly more efficient to-day because he uses his senses and thoughts in a transcendental manner for practical purposes.

We may be bold to predict from the foregoing that out of the present chaos that calls itself democracy a system will arise in which faithfulness, honor, loyalty and truth will be the goals, that the strong will protect the weak, that things will synergize and harmonize, so that the power of darkness will be overcome. Such a conclusion seems as comforting as it is irresistible.

## Igneous Concentration of Metallic Values from Mixed Sulphides

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—It is not easy to find an excuse for arithmetical errors such as occur in my paper on Igneous Concentration of Metallic Values from Mixed Sulphides, published in your journal, May, 1914, page 307. When such errors are found, the most fitting apology is a correction. Will you help me apologize to your readers by printing the corrected tables?

TABLE I

| COMBINED WITH | | GIVES | AND EVOLVES |
|---|---|---|---|
| One Lb. of | Lb. of | Lb. of | B.T.U. |
| Zinc | Oxygen<br>0.246 | $ZnO$<br>1.246 | 2,349 |
| Iron | Oxygen<br>0.286 | $FeO$<br>1.286 | 2,111 |
| Copper | Oxygen<br>0.252 | $Cu_2O$<br>1.252 | 1,067 |
| Copper | Oxygen<br>0.126 | $CuO$<br>1 126 | 6,197 |
| Carbon | Oxygen<br>1.333 | $CO$<br>2.333 | 4,374 |
| Carbon | Oxygen<br>2 667 | $CO_2$<br>3 667 | 14,580 |
| Hydrogen | Oxygen<br>8.000 | $H_2O$<br>9.000 | 52,254 |
| Sulphur | Oxygen<br>1.000 | $SO_2$<br>2 000 | 3,895 |
| Oxygen | $Zn$<br>4 062 | $ZnO$<br>5.062 | 9,540 |
| Oxygen | $Fe$<br>3.500 | $FeO$<br>4.500 | 7,391 |
| Oxygen | $Cu$<br>3.975 | $CuO$<br>4 975 | 4,041 |
| Oxygen | $Cu$<br>7.950 | $Cu_2O$<br>8.950 | 4,929 |
| Oxygen | $C$<br>0.750 | $CO$<br>1 750 | 3,280 |
| Oxygen | $C$<br>0 375 | $CO_2$<br>1.375 | 5,464 |
| Oxygen | $S$<br>1 | $SO_2$<br>2 000 | 3,895 |
| Oxygen | $H$<br>0 125 | $H_2O$<br>1.125 | 6,532 |
| Iron | $S$<br>0.554 | $FeS$<br>1 554 | 771 |
| Zinc | $S$<br>0 492 | $ZnS$<br>1.492 | 1,191 |
| Copper | $S$<br>0 503 | $CuS$<br>1.503 | 286 |
| Sulphur | $Zn$<br>2.031 | $ZnS$<br>3 031 | 2,419 |
| Sulphur | $Fe$<br>1 750 | $FeS$<br>2 750 | 1,350 |
| Sulphur | $Cu$<br>1 988 | $CuS$<br>2 988 | 569 |
| Sulphur | $Cu$<br>3 975 | $Cu_2S$<br>4 975 | 1,142 |

TABLE II

| COMBINED WITH | | GIVES | AND EVOLVES | ALSO GIVES | EVOLVES | TOTAL | ABSORBS | NET |
|---|---|---|---|---|---|---|---|---|
| One Lb. of | Lb. of | Lb. of | B.T.U. | Lb. of | B.T.U. | B.T.U. | B.T.U. | B.T.U. |
| $ZnS$ | $O$<br>0 495 | $ZnO$<br>0 835 | 1574 | $SO_2$<br>0 66 | 1285 | 2859 | 798 | 2061 |
| $FeS$ | $O$<br>0 650 | $FeO$<br>0 818 | 1342 | $SO_2$<br>0 728 | 1118 | 2761 | 491 | 2270 |

To burn completely 1 lb. $ZnS$, requires 0.495 lb. of oxygen for zinc and sulphur, and develops 2061 B.T.U. of available heat.

To burn completely 1 lb. $FeS$, requires 0.650 lb. of oxygen for iron and sulphur, and develops 2270 B.T.U. of available heat.

To burn 1 lb. of carbon to $CO_2$ requires 2.667 lb. of oxygen and develops 14,580 B.T.U. of available heat.

To burn 1 lb. of carbon to $CO$ requires 1.334 lb. of oxygen and develops 4374 B.T.U. of available heat.

It then requires about 7 lb. of $ZnS$ to replace 1 lb. of pure carbon burnt to $CO_2$, but only about 2 1-8 lb. if burnt to $CO$.

Heat developed per lb. of oxygen for $ZnS$ is $\frac{2061}{0.495} = 4164$ B.T.U.

Heat developed per lb. of oxygen for $FeS$ is $\frac{2270}{0.650} = 3492$ B.T.U.

Heat developed per lb. of oxygen for $C$ to $CO_2$ is $\frac{14,580}{2.667} = 5467$ B.T.U.

Heat developed per lb. of oxygen for $C$ to $CO$ is $\frac{4374}{1.331} = 3280$ B.T.U.

In a certain sense these errors are not important, as I was more concerned with the greater importance of utilizing as fully as possible the fuel values of various constituents of mixed sulphides, than with the publication of exact values in unfamiliar units.

The tables were compiled under conditions which prevented me from checking the results in the customary way.

F. L. CLERC.

Estes Park, Col.

## Is There a Complex Ore Problem?

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—On reading Mr. Lewis B. Skinners' contribution to the discussion on the above subject in your June issue, I was much surprised to find the following statement: "In passing, as there are fads in metallurgical lines as well as in others, I might note that we are going through a stage when the whole fraternity is on the *qui vive* trying to make every ore amenable to treatment by some flotation process. In the case of one-mineral separation in the United States this process has proven an aid; but it is of no benefit in the case of ores of zinc, which are truly complex, although being advocated for such. I do not know of any complex ore in Colorado, for instance, that could possibly show any advantage under this treatment."

It may surprise Mr. Skinner to hear that no fewer than four flotation processes, viz.: Potter, Delprat, Minerals Separation, and DeBavery, were invented for the express purpose of treating complex zinc ore at Broken Hill, Australia, and that during the last ten years several million tons of zinc-lead-silver ore and tailings have been profitably treated by these processes. As I was employed in mills using these processes at Broken Hill eight years ago I know whereof I speak.

I would like to see some of that "complex ore in Colorado that could not possibly show any advantage under this treatment." It might be worth while to have some experiments made with it.

Enormous strides have lately been made in "selective flotation" at Broken Hill (apart from the Horwood process), about which nothing has been published, and about which little or nothing is known in this country.

I might mention that the Murex process (not strictly a flotation process) is treating very complex zinciferous slime at the State mines in Germany.

W. MOTHERWELL.

Humboldt, Arizona.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Having followed with great interest the discussion of the complex-ore problem in recent numbers of your magazine I feel impelled to add my mite by way of comment on a few points.

I. Is there a complex ore? Or, going for instruction to the English dictionary, is there an ore "composed of several parts or components; knit, woven or folded together; involved, complicated, intricate; an aggregation; a number of metals combined into one grain or crystal?" All agree that there is. The question in my mind is: Is there a single ore that is not complex?

Is there a complex-ore problem? For more than thirty years of practice, study and experiment in the treatment of refractory ores, mainly by concentration, I have faced that problem. It is ever with us here in Colorado. We are getting more light, helps—among which such discussions as this are valuable—improvements in methods and machines; yet the problem is still here, complex indeed, inasmuch as almost every individual ore body calls for a separate solution.

Not only are many ores complex, but they call for a complexity of conditions in their treatment. I have found minerals of five different specific gravities in one ore on one table.

2. A great improvement might be made by employing or educating skilled operators. We have too few operators who are students, working with heart and mind for the success of the mill rather than for tally time and pay day. How shall we get them? Where shall we make them? That is a problem also, or perhaps a different phase of the same problem of complex-ore treatment.

3. Undoubtedly there are many mines now idle which would pay under careful and skilful management. If we would systematize our mills better, cut out the idea of "foolproof" machinery and employ at a premium a few interested, skilled and studious men who will work not only for salary but for success; cut out the idea of a big tonnage as the first essential (especially where it is impossible to get it with existing capacity of mine and mill) and hold to the idea of closest saving of mineral values and economy in all lines, we should have less idle mines, less decaying mills, monuments of failure and loss.

4. As to the element of complexity in different ores, let us consider a body of tellurium, for example. Good concentration will recover a fair percentage of values. Some of the tellurium will float and may be recovered by a method of flotation. Other values are like clouds of smoke and here cyanide gets in its work, providing the ore is oxydized or amenable to cyanide treatment. Occasionally there are particles of free gold and to save this we must amalgamate, concentrate or blanket—perhaps all three. We find pure gold bound up in grains of quartz so fine that after passing through a screen 100 meshes fine they still defy cyanide to penetrate and find their value; yet here good concentration by use of slimers and carpets will do much. The use of the glass to detect the losses is very essential. Then in many telluride ores very fine sulphides carrying high values are bound up in apparent gangue, calling for fine grinding and pebble mills and possibly oil flotation. Have we not here a complex condition, a complexity of methods, a complex problem calling for skilful intelligent handling?

5. A lead-iron-zinc-sulphide ore is, of course, complex enough to start with. Where a good concentrator will make good smelting values and at the same time cut out a middling product of iron cubes containing some zinc and traces of lead too low to pay its way, a late cyanide process has extracted 87½ per cent of the values with a 2½ per cent solution. I believe it would work on electrostatic iron as well.

An iron and free milling ore contains grains of quartz whose value will sometimes exceed the value of the heads. These can be cut out by a good concentrator and reground, occasionally in small mills and continuously in large ones, with good results.

When we go into the milling of refractory ores with knowledge of the problem before us and with a definite aim and plan of procedure, when we throw prejudice aside, when we make careful preliminary tests before installation and follow the test lines, when we employ conscientious and capable engineers who know what is required and are as anxious for our success as for our money, when we pick out efficient men for operators and give them the support that Carnegie gave and Edison gives to his men, then we shall begin to solve the problem.

6. The use of the microscope seems to me indispensable in the concentrating mill. An operator who is interested in his work and a student should be the possessor of the best pocket glass to be had. It will keep him posted as to many things. With it he can determine how clean his tailing sands are from attached mineral, with it he can be sure of the product he is making. In fact, every mill foreman should have a glass, a buckboard, pan and screens at hand for occasional pan and grinding tests, to be followed by assays, that he may know just what he is doing. But the first duty is to save the mineral which is freed, and until those "higher up" are interested to correct faults in the primary work the man running his shift is not likely to bother much about results.

Many pages might be written on the questions outlined and facts stated as to actual practice which are unbelievable, but the subject has already been thoroughly and ably handled. Such inquiries and discussions are in the right line. We hope to have more. We are in need of an army of thinkers and students to work out the many sides of the problem.

Ira F. Monell.

Boulder, Colorado.

## Heavy Mexican Oil as Fuel

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Mr. R. M. Chatterton's recent communication as set forth on your pages 364-5 of your June issue is most interesting and helpful to those making power for electrochemical purposes.

Concerning my comments before the American Electrochemical Society, etc., it is not the possibility of using oil engines to operate on heavy Mexican fuel oil that I brought forth, but rather that such is now the fact and has been for some years past. It is true that Diesel oil engines in Texas do not operate successfully on heavy Mexican oil 18 deg. Beaumé or less, and it is well known that to operate well the Diesel engine must utilize the higher-grade fuel oils. There is, however, an improvement on the Diesel oil engine which has all its advantages, namely, high economy, less attendance than a coal power plant, etc., and which is burning these heavy Huasteca oils containing as much as 60 per cent asphaltum, and doing it successfully. A 1000-kw plant of these heavy Mexican oil-burning engines is in operation.

Records taken from one of these plants and comparison with Mr. Chatterton's gas-power plant for the same load-factor, 0.73, are here recorded. The crude oil costing 2.68 cents per gallon.

*Cost per Kw-hr.*

| | Coal or oil fuel | Attendance | Supplies | Fixed charges | Total |
|---|---|---|---|---|---|
| Gas power plant.. | 0.34 | 0.266 | 0.0282 | 0.470 | 1.104 cents |
| Oil engine plant.. | 0.177 | 0.175 | 0.0282 | 0.355 | 0.733 " |

From the above it is evident that crude oil for fuel for the oil engine would cost 3.75 cents per gallon before it would equal the cost of the producer gas equivalent with coal at $3.50 a ton. As there is no producer, and no manual firing to be done, the labor is decreased by one-third. The supplies are about the same. Fixed charges are less, as the initial cost is lower, space occupied is less, and there is no producer to deteriorate. In fact, the engine and a tank of oil being practically the entire power plant. The oil engine referred to is the De La Vergne.

New York City.

## The Western Metallurgical Field

### Smelting Furnace for Cyanide Precipitate

In a paper presented at a recent meeting of the Columbia local section of the American Institute of Mining Engineers, held at the State College of Washington, Pullman, Washington, Mr. P. S. Anderson, of Baker, Oregon, submitted some notes on a smelting furnace for cyanide precipitate. He anticipated that the matter would be of interest to operators of small cyanide plants where the installation of more expensive tilting furnaces is not practical. The furnace is described as being well adapted to the Taverner lead-smelting process, which the author had used for many years with good results. The last furnace was in use nearly four years. It was built in a car body, dimensions 24 in. by 42 in., and the brick work had to be replaced about every twelve months. Mr. Anderson's notes briefly described the construction and operation. The furnace is charged with about 100 lb. of cyanide precipitate, litharge and flux, approximately 70 lb. damp precipitate being used. As this melts down, more is added until there is about 7 in. of molten material in the furnace. After stirring, and when the slag is fluid, the first tapping of slag is taken off if necessary; otherwise, scrap consisting of old cupels, speiss, etc., is added, and fusion completed. In tapping, about two-thirds of the slag is taken off in the mold, and the remainder of the charge is heated until the cupel, on testing with a rod, feels smooth. Then the entire remainder of the charge is poured into a mold. After cooling, slag and speiss are removed, and the lead bar is placed in the furnace for cupelation.

Although lead is allowed to go to waste, there is a compensating advantage in the fact that slag and bullion are cleaner. Very little gold is found in the flue-dust, although there is considerable silver. Samples give average results of 12.10 oz. gold and 1140 oz. silver per ton. Slags assay, on an average, two cents per pound in gold and silver. Gasoline consumption is about one gallon per 18 lb. of precipitate, including cupelation and resmelting.

### Oil-Fired Blast Furnace in Washington

An oil-fired blast furnace has been erected at the Copper King mine, Chewelah, Washington, by J. J. Anderson, patentee. A description of this type of furnace and some data on experimental operation were given in this journal, September, 1912, page 543. It is believed that this is the first furnace of the kind installed in the Northwest for smelting copper ore on a commercial scale. For some time experiments were made at Van Anda, Texada Island, British Columbia, under the metallurgical direction of Mr. Thomas Kiddie, formerly superintendent of the Northport Smelting & Refining Company's works at Northport, Washington. At his suggestion Mr. Anderson made improvements in the furnace, based on the experience gained in the trial demonstrations at Van Anda. Several runs were made, of a few days each.

The present installation at Chewelah is expected to be in continuous operation, and the results will be looked for with much interest. The capacity of the furnace is said to be about 100 tons per day. As the United Copper Company is reported to have more than 7000 tons of 5 per cent copper ore ready for smelting, there will be no lack of suitable material and the furnace will be given a fair trial.

### Motherlode Sheep Creek Mill, British Columbia

At a recent meeting of the Western branch of the Canadian Mining Institute, Mr. W. P. Alderson, general manager of the Motherlode Sheep Creek Mining Company, presented some notes on the operation of the company's mill, from which the following data are taken. The ore consists of partly oxidized quartz and quartzite and is treated by an oil-sliming cyanide process. The mill is equipped with 10 stamps and Merrill cyaniding apparatus. Power is generated by six Pelton wheels. The following figures have reference to a three-month period.

| | |
|---|---|
| Tons of ore milled | 8781 |
| Average value per day | $13.37 |
| Tons ore milled per day | 98.3 |
| Tons milled per stamp per day | 9.83 |
| Percentage of time run | 98.1 |
| Pebble consumption per ton ore milled, lb | 4.84 |
| Cost of pebbles per ton ore milled | $0.08 |
| Extraction by amalgamation, per cent | 72.1 |
| Total extraction, per cent | 97.1 |
| Precipitation: | |
| Tons solution precipitated | 14,957 |
| Tons solution precipitated per ton ore | 1.7 |
| Value solution, per ton | $1.97 |
| Tailing: | |
| Total value | $3,336.78 |
| Average value per ton | $0.38 |
| Chemical consumption per ton ore milled: | |
| Potassium cyanide, 98 per cent, lb | 1.84 |
| Lime | 2.17 |
| Zinc | 0.31 |
| Total cost of chemicals | $0.38 |
| Cost of milling, per ton: | |
| Labor | $0.515 |
| Supplies | 0.674 |
| Sundries | 0.212 |
| Total | 1.401 |

### Chlorination at Park City, Utah

Since publishing a description of the metallurgical work of the Mines Operating Company, Park City, Utah, in our issue for July, 1914, page 431, we have been advised that the process has been improved by the addition of a refining method that yields high-grade silver bullion from the base precipitate of silver, copper and lead. This is a step that is expected to add to the profit of treating low-grade ore containing several metals, and we are glad to record the reported shipment of about 20,000 ounces of silver of 975 fineness. Formerly all of the valuable metals were precipitated as a base sludge and sold without refining, but silver is now separated.

Another chlorination mill in the Park City district, which is expected to be in operation in August, is that of the Park City Milling Company. This is a custom mill which will treat ore from the American Flag and other near-by mines. The process is similar to that used at the mill mentioned above, and the success attained at that mill is encouraging to the promoters of the custom plant. The latter was remodeled from an old dry concentrating mill where the Grasselli Chemical Company produced zinc concentrates from the tailings of wet concentration.

### Dry Concentration and Flotation at Joplin

Coincident with the reported failure of dry concentration in the Joplin district comes the statement that the flotation process is to be given a thorough trial within the next few months. The mill of the Clifford Dry Concentrating Company was erected at Duenweg about a year ago, and was modeled along lines entirely foreign to ordinary local practice. Whether it was in the hands of incompetent operators or whether the process was wholly unsuited to the conditions, it is certain that the results were disastrous and little or no concentrates were ever produced. Flotation, however, is now in use in the Joplin district, and experimental work will be continued throughout the summer. Representatives of the state and national Bureau of Mines are said to be investigating the process, particularly in connection with a more perfect recovery of zinc.

The state of Missouri has made plans for the representation of its mining industry at the Panama-Pacific exposition in San Francisco next year. A sum of $6,000 has been appropriated for making a suitable display which will include model operations of drilling, mining and concentrating. The latter will be illustrated in a 25-ton plant. Lead and zinc smelting methods will be shown by means of models, photographs and finished products, and other operations related to mining and metallurgical industries will be displayed. The arrangement of the exhibit will be under the direction of Mr. Otto Ruhl.

### Aurora Consolidated Sold

As a result of competitive bidding on the part of a number of mining companies the property of the Aurora Consolidated Mines Company, of Aurora, Nev., has passed into the control of George Wingfield, president of the Goldfield Consolidated Mines Company. The consideration is reported to have been about $1,000,000. The Aurora property is one of the important mines of Nevada, and is located in a district that has a record of large production. In addition to the mine there is a 500-ton all-climing cyanide mill which is now in operation. The ore is said to have a gross average value of about $5 per ton in gold, and to yield a 92 per cent recovery by the process adopted. The vendors were Jesse Knight, of Provo, Utah, and his associates.

### Consolidated of Carnotite Companies

As a result of the organization of the Consolidated Ores Company in Salt Lake City, nearly all of the carnotite deposits in the state of Utah have passed into the control of that company. The interests thus united are those of David Taylor & Co., the Unarium Mining Company, and the Moab Rare Metals Company. Over 125 claims of carnotite-bearing ground pass into the control of the new organization. Up to the present time all ore taken from these claims has been sold in Europe, but it is now the intention of the company to investigate at once the methods of treatment for low-grade ores, which continuing to market the high-grade material abroad.

### Resumption of Smelting in Mexico

A matter of importance to the metallurgical industry is the reported resumption of smelting operations by the American Smelting & Refining Company at Chihuahua and other points in Mexico. It will be recalled that the company closed all of its plants in Mexico as a result of the revolutionary conditions and the consequent disturbance in transportation and other facilities for carrying on its business. Recently, however, the company has been ordering members of its technical staff to return to the smelting plants, and it is the intention to resume operations as rapidly as conditions will permit. The Chihuahua plant probably will be the first to be blown in, as it lies in northern territory and is less subject to disturbance. This will be followed by Monterey and Velardena, but the plant at Aguas Calientes may not be opened for some time.

### Company Reports

**The Buffalo Mines Co.**, Cobalt, Ontario, Canada, operates a concentrating mill for the treatment of low-grade silver ore. The sand tailing is stored awaiting the probable erection of a cyanide plant; the slime tailing is cyanided; and the concentrates from jigs and tables, and precipitate from cyanidation are treated by a special process of cyanide-amalgamation. From the report of the company for the annual period ended April 30, 1914, the following metallurgical data are taken. The average silver content of ore milled was 25.31 oz. per ton. The mill treated 77,616 tons and recovered 76.14 per cent by concentration. The cyanide annex handled 13,388 tons of slime tailing which contained an average of 10.13 oz. silver per ton, and made a recovery of 77.8 per cent. The cyanide-amalgamation plant and refinery treated 20 tons of high-grade ore taken directly from the mine, 301 tons of jig concentrate, 923 tons of table concentrate, 6157 lb. of metallics from the mill and 17,347 lb. of cyanide precipitate. The total production of refined bullion was 1,682,759 fine ounces silver. The price received for silver during the year averaged about 59.5 cents per ounce. The cost of producing silver was 35.7 cents per ounce. The cost of concentration based on handling 77,616 tons of ore, was $1.41. Cyaniding cost $4.03 per ton of dry slime cyanided, or $0.71 per ton of original ore.

---

## The Iron and Steel Market

July has not altogether kept pace with June in exhibiting an improvement in the iron and steel market, but the improved conditions of June have practically continued through July, and this itself indicates an improvement in fundamental conditions, for July is normally a very dull month and a decided recession in activity would ordinarily be expected.

The first definite improvement in the buying of steel since the movement which began late in December and played out in February, began about June 1. For several months preceding shipments of steel exceeded the current orders, until the supply of old orders was practically exhausted and late in May steel production fell to a rate of somewhat less than 60 per cent of capacity. In June and July shipments have been at about 65 per cent of capacity, July having perhaps a slight advantage over June, while the bookings of orders for prompt shipment fully supported this rate of production.

Of contracting for forward delivery there was relatively little in June, while in July there has been a very fair movement, chiefly in contracts for third quarter. In the case of agricultural implement steel bar tonnage there has been general contracting through the year, and in many instances for the first half of 1915 as well. The total implement tonnage, however, has been relatively small, as much contract business was carried over July 1, contracts for the preceding twelvemonth having been very poorly specified. To a limited extent the automobile trade has contracted in sheets and other steel products through the early months of 1915. In the case of all the contract business extending into 1915, and in the case of a considerable part of that closed only for third quarter, advanced prices have been secured over the level prevailing for prompt shipment.

The steel mills in western Pennsylvania and Ohio, finding themselves in moderately comfortable position as to the volume of prompt business on hand, and with a considerable volume of contract business at advanced prices, announced an advance of $1 a ton in bars, plates and shapes, about July 21, making the basis 1.15 cents, Pittsburgh. The Chicago district mills had been a trifle under the Pittsburgh basis, quoting an arbitrary of 15 cents per 100 lb. over the Pittsburgh basis instead of the full freight of 18 cents, and in that district there has been a slight tendency to advance prices proportionate to the Pittsburgh advance. The extreme Eastern mills have also shown a tendency to advance. More clearly than a month ago there is a zone market in steel products, the outlying districts not obtaining the full Pittsburgh price plus freight. The development of zone markets almost always occurs when demand is light and prices are now, the Pittsburgh basis being restored, as to practically all territory, when the market becomes active and strong. At this time, however, some doubt exists whether the Pittsburgh basis will ever come into full force again as to all products.

Effective July 20 the American Steel & Wire Company advanced wire products $1 a ton, to a basis of $1.55 for nails, independents promptly concurring. As usual, contracts had been booked with the large jobbers, providing for specifications to be filed within sixty days. The regular fall movement is about to begin, and if specifications upon old contracts are stimulated as expected, another advance will probably be made in the first half of August.

These advances represent the first sign of an upward tendency in steel prices since the beginning of February, and with a seasonable expansion in trade in August, coupled with good influences expected from the enormous crops in prospect the steel trade may be found not simply to have made a little turn for the better but to have entered upon a period of important improvement. Stocks are very low throughout the country and in such circumstances it usually requires only a definite start to be recorded in order to bring about a general buying movement.

### Pig Iron

The pig iron buying movement which started about June 1 did not attain the proportions which would ordinarily be expected. June was no more than a fair month for buying, while July has been relatively dull. Prices have been almost stationary, except for a decline of 25 cents in Southern iron. The technical position of the pig iron market is fairly good, with prices so near the cost of production that there can hardly be any further important declines, while production and consumption are about balanced. Prospects naturally are for an increase in consumption rather than a decrease after such a long period of liquidation, and the idle furnaces, as a rule, will have to be tempted by higher pig iron prices before they will go into blast. Three or four merchant furnaces in the Central West, however, have under consideration the taking of chances for an advance, and getting into blast for the purpose of piling iron. The market is quotable as follows: No. 2 foundry, f.o.b. Birmingham, $10 to $10.25; delivered Philadelphia, $14.25 to $14.50; f.o.b. furnace, Buffalo, $12.75 to $13; f.o.b. furnace, Chicago, $14; f.o.b. valley furnaces (90 cents higher delivered Pittsburgh) Bessemer, $14; basic, malleable and No. 2 foundry, $13; gray forge, $12.50 to $12.75.

### Steel

There has been a great deal of price adjusting on contracts for billets and sheet bars and very little in actual transactions. The market definitely weakened early in July, with freer offerings by steel mills and at reduced prices, but at the close of the month a slightly firmer tone is reported. The market is quotable at $19 for billets and $19.50 for sheet bars, f.o.b. maker's mill, Youngstown, and at $19.50 for billets and $20 for sheet bars, f.o.b. maker's mill, Pittsburgh. Rods are about $25, Pittsburgh.

### Finished Steel

Bars, plates, shapes and wire products are $1 a ton higher, as already indicated. Quotations are f.o.b. Pittsburgh, unless otherwise quoted, but in western and eastern territory the Pittsburgh basis is not fully observed.

Rails, standard sections, f.o.b. mill, except Colorado, 1.25c. for Bessemer, 1.34c. for open-hearth.

Plates, tank quality, 1.15c.

Shapes, 1.15c.

Steel bars and bands, 1.15c., base.

Iron bars, 1.25c., Pittsburgh; 1.17½c. to 1.20c., Philadelphia; 1.05c., Chicago.

Sheets, blue annealed, 10 gage, 1.35c.; black, 28 gage, 1.80c.; galvanized, 28 gage, 2.75c.; painted corrugated, 28 gage, 2.00c.; galvanized corrugated, 28 gage, 2.80c.

Steel pipe, ¾ in. to 3 in., 80 per cent off list.

Steel boiler tubes, 3½ in. to 4½ in., 72 per cent off list.

Wire nails, $1.55; smooth fence wire, 1.35c.; galvanized barb wire, 1.95c.

Standard railroad spikes, 1.40c., Pittsburgh; 1.50c., Chicago.

Structural rivets, 1.55c.; boiler rivets, 1.65c.

Cold-rolled shafting, 67 to 68 per cent off list.

Chain, ⅜-in. proof coil, 3.00c.

---

## The Iron and Steel Institute

The annual meeting of this institution was held on the 7th and 8th instant in London under the presidency of Mr. **Adolphe Greiner**, whose address dealt mainly with the by-products of steel manufacture.

With regard to coke ovens, he said, they now worked for something else than the silvery metallic looking coke of the Durham beehive ovens. The resulting gas was formerly employed almost entirely for heating the ovens, but on account of its richness it was more profitably employed for metallurgical purposes and for lighting. It might in future be used for the production of nitric acid and, possibly, also for the hydrocarbons from which it was expected the synthesis of artificial rubber would be effected.

He advocated the removal of dust from blast-furnace gases, and eulogized the work of Mr. B. H. Thwaite, who demonstrated the advantage of the direct use of those gases for the production of electrical energy. There was a considerable number of metallurgical works running between five and ten blowing engines and from ten to fifteen generators, some of them showing an aggregate output of over 30,000 hp, for which coke-oven gas, blast-furnace gas, or both, were utilized. Valuable economy, to the extent of 10 to 15 per cent results from using the heat of the exhaust gases for steam raising.

Besides the gases there were also slags which were already being used for making a kind of Portland cement, and also for bricks.

There was still much to be done in modern steel works in effecting economies by utilizing heat which was now lost. Engineers might some day solve the problem of avoiding the tremendous heat losses now incurrent in the converters; and heat losses by radiation from reheating furnaces and so on would repay their serious attention. Again many rolling mill steam engines—particularly in reversible mills—discharged into the atmosphere large volumes of steam which might be profitably utilized in low-pressure turbines.

If metallurgical works produced in regenerative ovens the whole of the coke required for the blast furnaces, and if the slag were used for making bricks and cement, and the waste gases were used for the production of motive power, he estimated that the resulting economy would amount to about 9s. 6d. per ton of pig iron, 11s. 2d. per ton of steel ingots, and 12s. 6d. per ton of rolled steel, and that without taking into consideration the sum yielded by the sale of basic slag.

---

**Montreal Meeting of American Chemical Society.**—The date of the Montreal meeting has been changed from Sept. 8-11 to Sept. 15-18, 1914 (Tuesday to Friday).

**Johnson Electric Zinc Plant.**—Johnson Electric Smelting, Inc., has contracted for power with the Mississippi River Power Company for a plant at Keokuk, Iowa, where the Johnson electric furnace for the smelting of complex zinc ores will be installed in commercial operation.

## Leipzig Meeting of the German Bunsen Society

The twenty-first general meeting of the German Bunsen Society for Applied Physical Chemistry was held in Leipzig from May 21 to 24. It was called to order in the morning of May 22 in the lecture hall of the International Exposition on Books and Graphics by the president of the Bunsen Society, Prof. M. LeBlanc. Speeches of welcome were made by Geheimrat Schmalz, of the Department of Education of Saxony; by Geheimrat O. Mayer, president of the University of Leipzig; by Dr. Dittrich, mayor of the city of Leipzig; by Dr. Volkmann, chairman of the board of directors of the International Exposition on Books and Graphics; by Geheimrat Weinstein, representing the Reichsanstalt and the Bureau for Testing Materials, and by Dr. Krey, who spoke for the German Chemical Society and the Association of German Electrical Engineers.

The Bunsen Medal was conferred on Prof. Walter Nernst, of Berlin, who being absent on a lecture tour in South America, had sent a paper on the application of his new thermodynamic principle to gases. This paper was read by Prof. von Wartenberg.

In the business meeting held on May 23 in the lecture hall of the Institute for Physical Chemistry of the University the new officers of the society were elected.

Prof. Hans Goldschmidt, of Essen-Ruhr, Germany, the distinguished inventor of the aluminothermic method, is the new president, his term running from July 1, 1914, to June 30, 1917. For the same period Prof. M. LeBlanc, of Leipzig, was elected vice-president. Geheimrat Dr. von Boettinger was re-elected treasurer.

HANS GOLDSCHMIDT,
PRESIDENT GERMAN BUNSEN SOCIETY.

Professor Goldschmidt, after expressing his thanks to the society, referred to the preponderance of scientists in the Bunsen Society. This is due to the difficulty which engineers have in presenting papers before the society. On one side they are exceedingly limited by commercial considerations in the extent to which they can discuss their work. On the other hand, they must avoid the appearance of speaking "pro domo," which means in this case "for their pocketbook." Nevertheless the presence of engineers in the meetings of the Bunsen Society and their mingling with the scientists is highly important; they can give and take. In recent years in both scientific and engineering circles in Germany there is felt a certain lack of able young assistants. In parenthesis Dr. Goldschmidt remarked that graduates of modern German woman universities have not the slightest difficulty in finding good positions in science as well as engineering, not for their looks but for their ability. But the demand for young able chemical assistants is now greater in Germany than the supply, and if this situation should continue it would mean a national calamity. In conclusion Dr. Goldschmidt referred to the work of Bunsen, who was a scientist but always sympathized with the work of the engineer. As many of his students have become engineers as scientists. The influence of the Bunsen Society should manifest itself in the same direction.

According to the report of the board of directors the number of members on April 1, 1914, was 792. The assets of the society amount to over $8,000.

The numerous papers presented at the meeting will all be published in full in the organ of the Bunsen Society, the *Zeitschrift für Elektrochemie*. Abstracts of the papers appeared in the issue of June 1, while publication of the papers in full has begun in the issues of June 15 and July 1 and is to be continued.

Dr. P. Klemm spoke on the application of the principles of physical chemistry to paper manufacturers, Dr. R. Rübencamp on printing colors, and Prof. E. Goldberg on engravings and special presses for engravings.

### Electroplating

An interesting review of the present status of electroplating was given by Dr. W. Pfanhauser, of Leipzig. He estimated that purely for electroplating work in Europe alone, 2,500,000 amperes are in use, and in the whole world 3,000,000 amperes. This corresponds to 15,000 tons metal deposited per year in electroplating (not including electrolytic refining). Thirty-five per cent of this work is done in Germany and Austria.

Besides nickel plating, zinc plating is now coming to the front. For zinc plating of wires, ribbons, and tubes, 300,000 amperes are now in use. The main interest of progressive electroplaters is at present directed toward improvements in mechanical appliances. But fundamental changes in the chemistry of electroplating may also come and the author thinks that the next chemical revolution will be the use of fused electrolytes.

### Indefiniteness of Atomic Weights

Two rather revolutionary scientific papers, both coming to the conclusion that the atomic weight of an element has not a definite value were presented by Dr. K. Fajans, of Karlsruhe, and by Prof. O. Hönigschmid, of Prag, respectively.

In his paper "on the final products of radio-active disintegration series" Dr. K. Fajans said that until recently it has been assumed that a chemical element has always the same atomic weight from whatever mineral it may have been isolated. But when a year ago the author and Soddy brought the radio-active elements in line with the periodic system, the hypothesis was suggested that there are elements which while entirely identical in chemical respects may differ in atomic weight up to eight units and which differ otherwise only by their radioactive properties (rays, speed of disintegration). This hypothesis was first based only on indirectly determined properties of radioactive elements of short life and it was therefore important to prove experimentally that two elements which appear to us to be identical chemically can have different atomic weights.

The author then concluded that this test could be made with lead. He considered it as probable that the atomic weight of lead formed in the course of millions of years in uranium minerals as the final product of the disintegration of uranium would be different from that of lead obtained from ordinary lead minerals.

This conclusion has been tested and has been fully confirmed by the author's former collaborator, M. Lembert, in the laboratory of Prof. Theo. W. Richards in Harvard.* Lead from uranium minerals was found to have the atomic weight 206.6, while ordinary lead has the atomic weight 207.1. The possible error is at most one or two units in the last decimal and is therefore much smaller than the difference found experimentally.

Of greatest interest is the fact that these two kinds of lead are not only chemically identical, but also identical in spectroscopic respect. On the basis of similar considerations it is probable that lead from thorium minerals has a higher atomic weight than ordinary lead. Possibly ordinary lead is but a mixture of lead from uranium and lead from thorium. The question comes up whether the atomic weights of most elements are perhaps only mean values of the atomic weights of several chemically identical elements which therefore cannot be separated by chemical means. Atomic weight researches have therefore to meet an entirely new problem; that is to investigate how the atomic weights of the elements depend on their origin.

The paper by Prof. O. Hönigschmid on a "revision of the atomic weight of uranium" gives the results of a determination by analysis of uranium bromide. His atomic weight of uranium is 238.18, that is 0.3 units below the present international value. He considers the value 226.4 for the atomic weight of radium to be improbable, since the difference between the atomic weights of uranium and radium must be at least 12, that is, 3 x 4 (atomic weight of helium). His own value Ra = 225.97 is therefore considered to be more probably correct.

At the same time the author determined, jointly with Stefanie Horovitz, the atomic weight of lead obtained from uranium ore and found 206.73, that is, 0.4 less than the atomic weight of lead obtained from ordinary lead ore free from uranium.

### Other Papers

Prof. E. Cohen, of Utrecht, spoke of the metastable state of metals. By dilatometric methods it has been found that the metals as we know them now are metastable and contain simultaneously several allotropic modifications. For this reason the metals are not in equilibrium at ordinary temperatures and gradually disintegrate. The author reported on new experiments in which he obtained by very sensitive electric methods the same results as by dilatometric measurements.

Prof. H. von Wartenberg, of Danzig, discussed the possibility of the existence of gaseous alloys; Prof. F. Fichter, of Basel, spoke on the Kolbe reaction with $HOOC{-}CH_2.SO_3H$; Prof. H. Goldschmidt, of Christiania, on the equilibrium between hydrogen ions, alcohol and water; Prof. A. Hantzsch, of Leipzig, on indicators; Profs. F. Haber and G. Just, of Berlin, on new experiments on the emission of electrons in chemical reactions; Prof. G. Bredig, of Karlsruhe, on the chemical kinetics of formic acid formation; Prof. H. Bechhold, of Frankfurt on Main, on the existence of colloidal solutions of sodium urate; Prof. R. Marc on the kinetics of adsorption; Prof. M. LeBlanc on the photobromination of toluol; Mr. N. S. Hatfield on some new electric apparatus (a hydrogen-electrode meter; a flame arc lamp with improved efficiency and diminished carbon consumption; a time switch without mechanism); Prof. O. Sackur on the equation of state of gases and the theory of quanta; Prof. W. Loeb on some fundamental chemical problems on the effect of high-tension electric currents on the growth of plants; Dr. G. Schulze, of Charlottenburg, on electrolytic valves; Prof. W. A. Roth, of Greifswald, on graphite, diamond and amorphous carbon; Dr. V. Falcke, of Leipzig, on the reaction between ferrous oxide and carbon and between ferric oxide and iron; Dr. A. Goldmann, of Leipzig, on the theory of the Becquerel effect; Dr. K. Schaefer, of Leipzig, on optical investigations of the constitution of inorganic acids, salts and ester; Dr. M. Volmer, of Leipzig, on photochemical sensitiveness and photo-electric conductivity; Dr. E. Wilke, of Heidelberg, on the Tyndall phenomenon, and Dr. M. Trantz, of Heidelberg, on two gas reactions.

Next year's meeting will be held in Karlsruhe, beginning May 13, 1915.

## The Non-Ferrous Metal Market

Beginning July 1 the non-ferrous metal market gave evidence of greater activity and firmer prices. This followed the marked depression during the latter part of June when prices fell off materially and sales were small. Copper and tin have benefited most by the change, while lead and spelter continue to remain quiet and fairly inactive.

**Copper.**—Prices for this metal advanced from the low figure of 13.20 @ 13.25 cents in the latter part of June to about 13.55 @ 13.65 early in July. The market stiffened and sales abroad were greatly increased, while local consumers also bought in larger quantities. Nevertheless stocks have increased, as shown by the report of the Copper Producers' Association for June.

**Tin.**—Favorable statistics on this metal published on the first of this month affected the market and added to the general tendency toward higher prices than prevailed in June. July tin is quoted at 32 cents in the domestic market.

**Lead.**—The New York market has remained firm but the Western market is somewhat lower in price and quiet. New York quotation is 3.90 cents, and St. Louis 3.72½ @ 3.75 cents.

**Spelter.**—Prices for this metal improved slightly from those of June, but the market is quiet and without feature. New York prices are 4.90 @ 4.95 cents, and St. Louis 4.75 @ 4.80.

**Other Metals.**—The market for aluminium is poor and sales are small. The metal is quoted at 17½ @ 18 cents per lb., New York. Business in antimony also is quiet, but prices are firm, ranging from 5.65 to 7.35 cents for various brands. Quicksilver is quoted at $37.50 @ to $38.50 for flasks of 75 lb., New York, and $37.50 at San Francisco.

**Specific gravity separation** applied to the analysis of explosives is treated in **Technical Paper 78** of the Bureau of Mines. The authors are C. G. Storm and A. L. Hyde.

**The Richards Pulsator Riffle** is an application of the Richards pulsator jib to riffles such as are used in hydraulic mining operations or on dredges for the recovery of gold. The ordinary Hungarian riffle consists of angle irons placed across a sluice or table at right angles to the flow of water and gravel. A section across the riffle appears like a series of inverted letters L. In cleaning up the accumulation of gold from the riffles, the angle irons are removed and the concentrate taken out by hand. By applying a pulsating current of water under these riffles, according to the principle of the Richards pulsator jig, an automatic riffle with continuous discharge is produced. This device has been tested by the manufacturers, the Denver Engineering Works Co., and found to give excellent results on placer sand and gravel.

# The Construction of the Blast Furnace Stack*

By J. E. Johnson, Jr.

*(Concluded from page 460)*

### The Shaft or Inwall

Above the mantle only two styles of construction have been used in recent years. For many years nothing but plain fire brick from two to five feet in thickness was used from this point to the top of the furnace, but the tendency for the lining to be eaten away more extensively just above the top of the bosh than anywhere else, which had existed very generally for many years became worse with the general use of fine ores, and the lining troubles which they brought with them.

As the cooling plate construction had given a good account of itself in the bosh, furnace-men began to put rows of cooling plates above the mantles to prevent this action, and this practice is now quite generally followed. These were at first simply built in the brick work and the pipes to them were brought in through small holes cut in the shell for that purpose. This, of course, put these cooling plates entirely beyond the possibility of renewal, if they failed they were done with and must be shut off and were soon burnt up.

To meet this situation some furnace men have cut holes through the furnace shell large enough to permit the removal of the whole cooling plate exactly as is done on the bosh, but this cuts up the shell very badly and even when this provision is made it is a matter of much difficulty to remove these plates through such a great thickness of brick work. It is, therefore, doubtful whether the trouble and expense of making these plates removable is worth the small gain to be obtained by that means. It will be seen that in the case of the furnace shown by Fig. 4* the course was adopted of bringing the water pipes for these blocks out through the shell so as to give access to the several connections but without making any provision for the removal of the cooling plates.

In early days of cooling plates they were made of cast iron with coils of pipe cast in them, these in all cases being built solid in the brickwork, without any provision for removal. The pipes were first made in one continuous coil zigzagging back and forth through the cooling plate, but an improvement on this was subsequently introduced which consists in making each pass of the pipe through the block separate and bringing the ends of all the pipes out through the outside surface of the plate, and putting the connections which put them in series on these projecting ends. By this means if the inside pipe failed it could be cut out and the one back of it left in service. Similarly if this failed by the gradual burning back of the furnace it in turn could be cut out and so on back for as many passes as the pipe might make through the plate, this number generally being from three to five. This arrangement is shown in Fig. 7.

For the protection of the bosh, hollow bronze cooling plates which do not adhere very tightly to the brickwork and on the inner surface of which the iron and slag do not burn fast in great lumps, so as to prevent their removal, were a great improvement, because they could be replaced as often as they failed and inside of the furnace kept practically to the original lines for a long period of time.

On account of this superiority for service below the mantle, the bronze cooling plate has often been used above the mantle also, but after considerable experience with it I prefer the cast iron plate with pipes cast in, for that service, for two reasons.

First, these plates above the mantle being the highest of any of the water-cooled portions of the furnace they are the first to lose the water in case of any partial failure of the water supply which reduces its head. I have known of several cases where this happened without the complete failure of the water supply. This means that these cooling plates above the mantle will lose their water first, and if they do so the bronze-plates are bad for two reasons. First the melting point of the bronze is many hundred degrees below that of the cast iron plate and its mass is much smaller, the body of the plate being hollow, so that when the water on these plates has been lost, even though the furnace be stopped at once, the heat of the surrounding materials will cause the bronze to melt after a comparatively short period, which leaves a considerable cavity in the brick work into which the bricks from above are likely to settle, thus causing at least the possibility of a crack in the lining, even though the gas does not blow out through the burnt cooling plate itself.

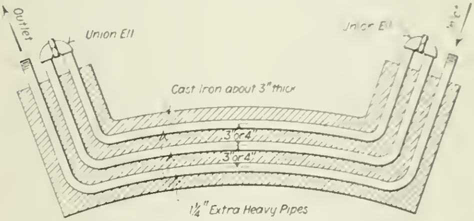

FIG. 7—CAST-IRON COOLING PLATE

With the cast iron plate, on the other hand, the conditions are quite different. The melting point of cast iron is not reached by the contents of the furnace at a point much above the mantle, so that these plates are much less likely to be melted out completely than the bronze plates, and even if the inner end next the stock is melted off the outer end is protected by the brickwork for a long time, if not indefinitely, and being practically solid except for the pipes cast through it a partial melting of the cooling plate does not form a cavity as in the case of the bronze plate.

Secondly, if even a small portion of the nose of the bronze plate be melted off it is destroyed completely, as this opens the water space into the furnace, but with the multiple pipe system several inches of the plate may be melted away and still, by using some of the outer passes of pipe, water may be put through it again, and its usefulness as a cooling member preserved indefinitely.

When these plates are installed, whatever kind may be used, provision must be made for obtaining access to them. In Fig. 4 two platforms for this purpose will be seen above the platform at the level of the mantle, these platforms being provided with a suitable handrail. This is important because in case of trouble with the circulation in these plates it is necessary to obtain access to them quickly in order to prevent their being burnt, and this cannot be done if ladders have to be arranged for the purpose. Moreover there is always a certain quantity of furnace gas stealing up the walls of the furnace, no matter how well it may be constructed, and while this may be so dilute that the workmen exposed to it will not realize the danger, he may nevertheless be made unconscious by it. Under such conditions, if working from a ladder he is almost certain to fall and be seriously injured or killed, whereas if a secure platform with a good handrail be provided he will fall upon this and can easily be rescued before further poisoning by the gas.

---

*Figures 1 to 6 were published in the instalment of the July issue.

The number of rows of cooling plates above the mantle is a matter of the individual conditions and the judgment of the operator. The customary number is probably from three to six rows, although in several cases these rows have been run all the way to the top of the furnace, spaced about as shown in Fig. 4. This is often done with furnaces intended to be run on ferro manganese or spiegel which are highly destructive of their linings. For ordinary furnace practice the consensus of opinion is that there is no advantage in having more than a limited number of rows of these plates.

There is a drawback to the use of these plates in that while they prevent the lines of the furnace from cutting back at the plate they do not prevent heavy erosion in the space between the adjacent rows very much as shown for the bosh in dotted lines in Fig. 3 and the steps so formed offer a lodgment for scaffolds in the very region of the furnace where the stock is in its pastiest condition and therefore most likely to scaffold. Consequently these steps tend to promote scaffolds with all their disastrous consequences.

For this reason some operators prefer not to use cooling plates above the mantle at all, but to let the lining wear away and cool the shell externally with sprays if it becomes necessary. It is stated by Mr. H. A. Brassert in his paper on Modern American Blast Furnace Practice read before the American Iron and Steel Institute, May, 1914, that "cooling plates above the mantles have only survived where they are placed from 18 inches to 22 inches back of the face of the inwall and in this position they have not much effect in preserving the original lines."

This statement may not be universally true, but may be considered as absolute proof that cooling plates above the mantle are not a panacea for lining troubles but on the other hand are only to be used sparingly and with great discretion.

From this region at the base of the shaft to a point a few feet below the stock line conditions of the temperatures and abrasion are such that well made fire brick alone will withstand a long campaign, and consequently in the great bulk of modern practice nothing else is used.

### The Stock Line and the Top of the Furnace

In this region the influences of chemical activity and temperature are greatly reduced over what they are in the lower portions of the furnace, but the lining is exposed to another form of attack which has proven almost as difficult to resist as that in the hearth and bosh.

This is the abrasive action of the stock as it is dumped from the conical bell into the furnace. The charge of coke in a modern furnace is from six to twelve thousand pounds, and in the best modern practice this is an extremely hard dense coke. In practically all cases also the limestone is in the form of lumps; sometimes this is crushed to go through a three or four-inch ring, but in many cases lumps which would scarcely pass through an eight-inch ring are tolerated, such lumps weighing up to twenty pounds.

When the bell opens these slide off its steeply inclined surface and strike violently against the walls of the lining at the stock line. In some cases also a considerable portion of the ore consists of hard lumps, some forms of ore having not only a high specific gravity, but also a degree of hardness comparable to that of granite, though these conditions are not usual in most present practice. These materials with their hard and abrasive nature inpringing on the stock line at a rate varying from one to two thousand tons per day cannot fail to exercise a destructive effect upon any brick work used for the lining, and as a consequence many forms of metallic protection have been used for this portion of the furnace.

The earliest form of protection known to me was angles of cast iron, six inches square on the face, six by nine inches in the body, by one inch thick. These were laid in fire clay on top of a course of brick work, and another course of brick work six inches thick built on top of them, then another row of angles was inserted, and so on. This armour extended for some eight or nine feet vertically in the furnace from a point two or three feet above the stock line to one seven or eight feet below it.

These after many years' trial proved to be unsatisfactory. The ends of the plates would break off and the protection of that area would be lost, but more serious still, cast iron swells when repeatedly heated and cooled through certain temperature ranges, and these are ranges which exist at the top of many furnaces.

It is probable, moreover, that a graphitization of the carbon in these plates occurs in consequence of their long heating, and this also is accompanied by swelling which tends to disintegrate the structure of the angle. Moreover, this swelling took place unequally at different points around the circumference of the furnace and the top of the brickwork was not only pushed up to an objectionable extent by the action but also at some points more than at others.

At other times and plants steel mantles or circular shields slightly smaller than the brickwork were hung inside the furnace at the stock line, but these failed because while the temperature at that point is not normally high enough to affect the structure of wrought iron or steel, it is high enough to cause those materials to warp very extensively in course of time, and if these mantles warped at all they must go inward since the brickwork close outside them prevented them from warping outwards. Such irregular projections of portions of the mantle into the furnace utterly destroyed the regularity of the stock line upon which the proper filling of the furnace depends, and brought about the very conditions which the mantle was introduced to avoid.

Cast iron or steel rings built up of segments were tried at some plants. These were built into brick work practically like a course of iron or steel bricks at intervals of two or three feet vertically, but as the stock has a considerable outward velocity as it leaves the bell these did not prevent it from cutting into the brickwork between them, and they, therefore, failed to fulfil the purpose for which they were intended.

I have never used these myself and I do not know of any case where they have been continuously used by any one plant for a long series of years.

One of the earliest successful means of solving this troublesome problem was an adaptation of the old cast-iron angles, first made by the writer so far as known to him, in 1903 or 1904, at the plant of the Longdale Iron Company.

After realizing the uselessness of the cast-iron angles, the suspended mantles, and various other schemes, it seemed likely that wrought iron being much lower in carbon than the cast iron, would be free from the tendency to grow by repeated heating and cooling, and would have also the physical strength needed to prevent breaking off the vertical portions of the plates in service. It would also be free from the liability to extensive warpage which had destroyed the steel shields because the individual angles, six inches square on the face, would have between them spaces of an eighth of an inch or so at the closest, and these spaces providing room for individual expansion would prevent objectionable warpage which was the result of the cumulative expansion of a considerable area of the mantle as a whole.

Accordingly a trial of such angles was made. These were made of three-quarter-inch by six-inch wrought iron, six inches square on the face, six inches by nine on the portion built into the brick work, and were successful far beyond our highest expectations. Instead of being compelled to reline the top of the furnace at the end of every campaign as had previously been the case, a furnace would make two or three campaigns without disturbing the upper portion of the lining.

Since that time these angles have been used with some modifications at a considerable number of plants, and always, to the best of my knowledge, with entire satisfaction and success. Modifications have been made in some cases. The portion of the angles built into the brickwork has sometimes been made long enough to go entirely through the brickwork, and the outer end turned up into a hook, this being imbedded in concrete poured around the lining at the top of the furnace. I have never seen any tendency for these angles to work out of the brickwork which would necessitate this additional construction.

There is, however, a very simple method of preventing this, if such danger were anticipated by a simpler and less expensive means. The leg of the angles built into the brickwork can be sheared to approximately the taper which will make them lie to the circle of the furnace. If the sides of the plates before bending were sheared to an unbroken straight line this would result in slight gaps between the turned-down portions or faces of the angles, but this would be a matter of no importance and the portion of the angle built into the brickwork, having its largest end out, would be absolutely prevented from working forward into the furnace.

It is something of a nuisance to level up the outside courses of the brickwork so as to bring them level with the tops of these angles, when the latter do not run clear through the wall, and to avoid this difficulty bricks of different thickness may be used on the inner row where the angles are laid. By using what firebrick makers call the standard thickness of brick in the courses on which the angles are to come, and the three-inch thickness in the rear courses behind them, the thickness of a three-quarter-inch angle is just about compensated with a minimum of difficulty in levelling up and without using any but standard material.

There are no patents on the use of these angles made of wrought iron or mild steel though a patent on their use when made of hard steel is held by Mr. E. B. Cook.

Another type of metal protection for the top of the furnace is one designed by Messrs. Albert Broden, manager of the Reading Iron Company, and Frank C. Roberts of Philadelphia. This is shown by Fig. 8 and consists of a cast steel sleeve the shape and size of the furnace itself at the stock line, which rests on cast steel brackets securely riveted to the shell.

The downcomer opening is cast through this sleeve and all brickwork is left out between it and the shell of the furnace proper. Large openings are cut through the shell to render the sleeve accessible for expansion and to provide air cooling for it. Water troughs are cast in its outer surface and provision made for a spray pipe around the top so that a continual trickle of water may be kept up over its surface in case of necessity.

The bottom section is cast separately and is cooled by water pipes cast in. This projects down inside the top of the brick work and protects the upper edge of the latter from the abrasion of the stock. The cooling water is trapped from the pockets in the back of the brackets, which are fastened water-tight to the shell and so prevent any possibility of water getting down through the brickwork. The joint with the hopper at the top is made by a single layer of brick laid in the usual way. This is an excellent construction and has given good results since it was put into service a short time ago. The only objection to it is the expense, being made of steel castings with accurately machined joints at all points where the different portions come together, the construction is a very expensive one.

### The Shape of the Top of the Furnace

It was formerly customary to run the shell practically vertical to the top, putting brackets in the inside to support the hopper ring and other brackets on the outside to carry the wheelway for the filling barrows.

In early days the hopper ring was not even bolted down to the brackets but with the greater frequence of violent slips which followed immediately upon the introduction of large percentages of fine ore into the burden, it was soon found necessary to have a more substantial construction. This was begun by making the brackets of steel instead of cast iron and bolting the hopper and hopper ring to them. Finally Mr. Julian Kennedy pointed out the general weakness of this construction and the necessity of holding the top of the furnace down until the violence of the slip had passed by. In fact he claimed that by preventing the release of pressure at the top the violence of the slips could be much diminished, and he was the first to introduce the coned top shown in Fig. 2 in which the shell is drawn in to support the hopper ring directly, thus making a much better and tighter joint between the hopper and the shell and giving a construction of sufficient strength to resist all ordinary slips and explosions.

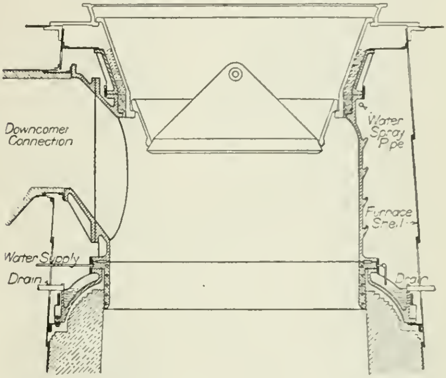

FIG. 8—BRODEN-ROBERTS STOCK LINE PROTECTION

The wheelway of the hand filled furnace is of course entirely eliminated as such, in modern mechanically filled furnaces, but an operating platform is provided, generally about as shown in Fig. 2.

The great mass of brickwork formerly put in above the bottom of the hopper is in fact perfectly worthless as it has no heat-resisting functions to perform and only serves to make a joint between the hopper and the furnace shell, and generally a very poor joint it was, having to be supplemented by clay packing, and accompanied by more or less leakage of gas, particularly during the blowing-in periods of the furnace when the gas is most deadly. The elimination of this construction has also resulted in putting the gas outlets further up toward the top of the furnace where they belong, somewhat as shown in Fig. 9 which is an elevation of the furnace shown in Fig. 2 and shows the location of the gas outlets more clearly.

### Thin-Lined Furnaces

It has been recognized for many years that fire brick exposed to the conditions in the blast furnace would wear back until the amount of heat carried off by their bases about equalled the amount brought in by their inside surface, after which time wear took place much more slowly. It has also been recognized that in the standard construction considerable life of lining can only be secured by a corresponding thickness, and that as this thickness wore away the departure of the furnace from its original and presumably correct lines became greater and greater, generally with more and more unsatisfactory working.

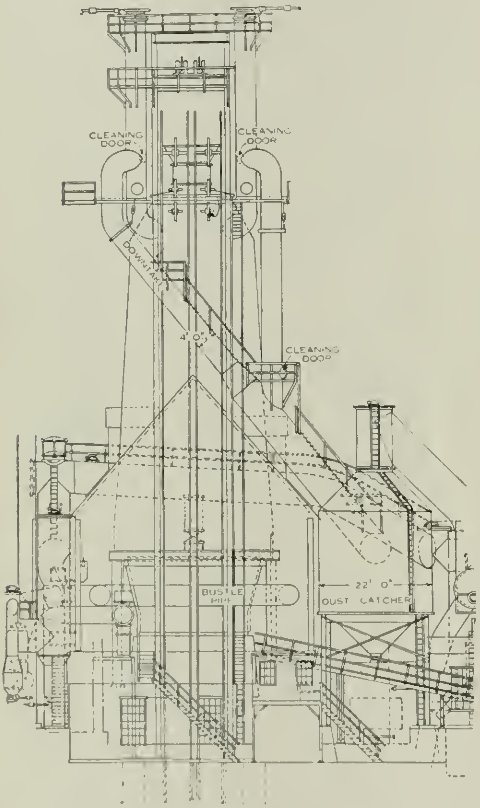

FIG. 9—ELEVATION OF BETHLEHEM STEEL COMPANY'S "A" FURNACE, SHOWING DOWN COMER

About fifteen years ago the experiment was tried in Germany with the idea of overcoming these difficulties of making the lining of the furnace exceedingly thin, only a few inches in fact, and cooling its exterior surface so as to maintain its original shape indefinitely. The idea has superficially much to recommend it, and after several years' trial in Germany it was introduced into this country, first at the Lucy Furnaces in Pittsburg, under the management of Mr. James Scott.

The German construction consisted of cast-iron staves with flanges on their exterior surface and jaws like flanges on the inside, into which the bricks were securely fastened. These were built up into a furnace shaft very much in the same way that the bosh jacket shown in Fig. 5 is built up, but the exterior was cooled by a water film or spray instead of the pipes cast in shown in Fig. 5.

The construction adopted at the Lucy Furnaces was different. There a steel shell was built much smaller in size in proportion to the lines of the furnace than the ordinary shell, since the thickness of the brick with which it was lined was only about one foot from top to bottom. On the outside of this shell were riveted annular troughs, each about two feet deep by six or eight inches radial width, and arranged so that water pumped into the top one flowed down through all the others in sequence to the bottom. In spite of great pains to secure absolutely air-tight construction, some water leaked into the furnace through the rivet holes and the results were unsatisfactory, though subsequently these difficulties were overcome.

Soon after this two thin-lined furnaces of this type were built at the Illinois Steel Works, and subsequently one of these was rebuilt with cast-steel plates instead of the boiler-plate shell and riveted buckets. This, however, did not prove satisfactory and the latter construction was restored. A bucket type of thin-lined furnace was also constructed at the plant of the American Steel & Wire Company in Cleveland.

A thin-lined furnace was subsequently built by the Detroit Iron and Steel Company according to the plans of their general manager, Mr. Max McMurray. This solved the problem of saving the original shell for supporting the top works of the furnace, which had not been done in any of the other constructions, columns having been run all the way up from the mantle to the top for this purpose.

In the case of the Detroit furnace the expedient was adopted of building a smaller shell with a thin lining inside the original shell and cutting a number of doors through to give access to the inner shell for examination, this shell being cooled directly by water sprays at the top forming a film of water which runs all the way to the bottom. The outside shell also presents the advantage of preventing the wind from blowing the water off the stack, thus leaving it dry on one side, and making a disagreeable spatter below, both very important points. This construction is shown by Fig. 10.

The Tennessee Coal & Iron Company have also had a thin-lined furnace in operation for a number of years. This was a very heavy boiler-plate shell with spray pipes arranged around the top. A series of galleries were arranged at different levels around this shell and outside these galleries was a sort of housing of steel slats to prevent spatter and to prevent the wind from blowing the water off the shell.

A different construction still has been used by Mr. Frank C. Roberts in a furnace built by him for the Warwick Iron Company, shown in vertical section in Fig. 11. In this the top of the furnace is supported by separate columns running up from the mantle, as previously described, and the shell is a boiler-plate shell, but instead of trusting somewhat to chance in the matter of the distribution of the cooling water around it, this is accomplished by a helical trough shown in larger section in Fig. 12.

The trough is supported by tap bolts which do not go all the way through the shell and, therefore, make leakage through it impossible. The bottom edge of the trough is spaced away from the shell by distance blocks as shown. Part of the water runs out the space at the bottom of the trough and that which cannot get out this way runs around the helical trough. In this way a perfect distribution of water is secured around the circumference of the shell and the danger of wind blowing the shell dry on one side is eliminated.

A compromise, one-half thin-lined and one-half standard construction has been in use for several years at the Port Henry Furnace of the Northern Iron Company. This construction shown in Fig. 13 is that of the former manager of the company, Mr. F. E. Backman, the design being carried out by Frank C. Roberts & Co. This furnace has a complete mantle shown in section resting on the vertical portion of the column at the level of the top of the bustle pipe. From this other columns run up on a slight inward batter to a second mantle some twenty-five feet higher. On this second mantle rests the upper portion of the inwall which is of standard construction. From this point down to the bosh there is a boiler-plate shell with rings of angles for supporting the brickwork riveted to its inside surface at intervals of five or six feet. This shell makes a joint on top of the cast-iron water-cooled segmental bosh jacket. The bosh jacket is lined with nine inches of brick and the nearly vertical portion of the shaft above it with thirteen inches.

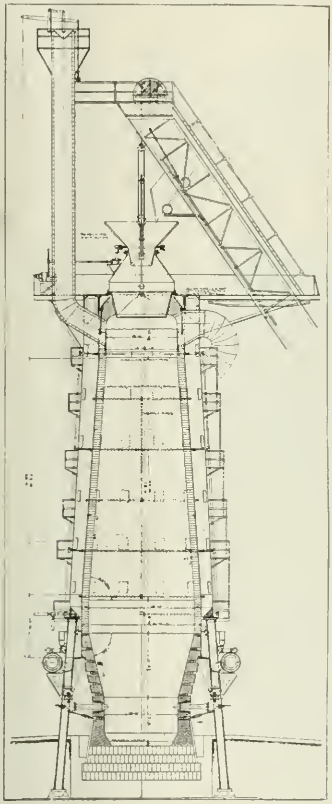

FIG. 10—DETROIT IRON & STEEL COMPANY'S THIN-LINED FURNACE

This construction is intended to prevent the gouging out of the lining above the top of the bosh which has been described above. This furnace has now been in operation for several years and is said to have given good satisfaction.

The conditions in regard to thin lining for the inwall or any point above the top of the bosh are vastly different from what they are below that point, because as already pointed out the convergent slope of the bosh provides a natural lodgment for the slag which runs down and chills upon its cooled surface in the normal operation of the furnace, so much so, that as before stated, if a furnace were started with an externally cooled bosh jacket entirely bare of bricks this would soon cover itself with a lining as good or better than the best fire brick which could be put upon it. But above the mantle the slope is in the other direction, the shaft of the furnace is a cone divergent downward, moreover except in its extreme lower portion there is no molten material, and if there were any it could not inpinge upon this outward flaring surface, and could

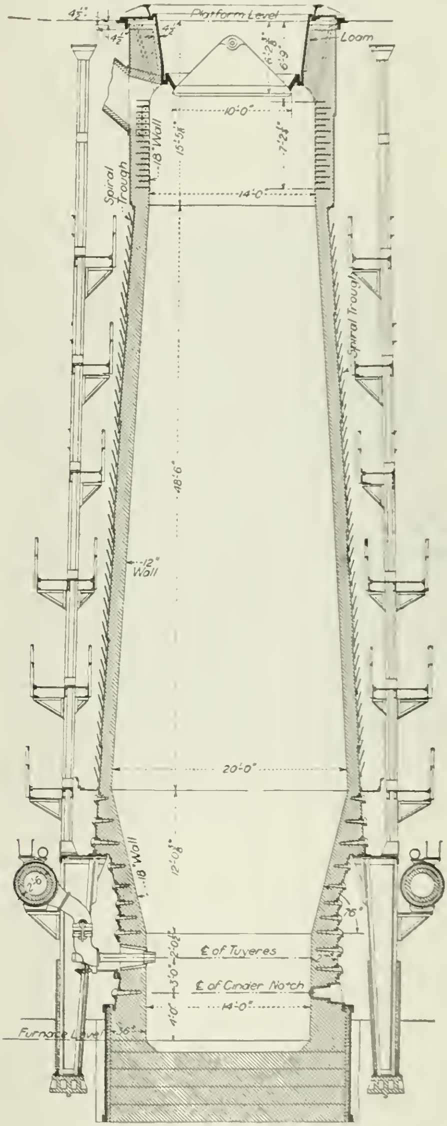

FIG. 11—SECTION OF WARWICK THIN-LINED FURNACE

not remain there if it did so. Therefore if the lining is once removed from this portion of the furnace it is gone for good and all, until restored by relining.

Moreover the furnace shell does not furnish much support in the vertical direction for any lining which may stand against it. It does prevent this lining from pushing out or falling backward, but it does not prevent its falling inward or sliding straight down in case of the failure of its support below. For this reason it seems to me necessary that the lining of the furnace above the bosh should consist of a sufficient thickness of brickwork to support itself and the portion of the lining above it. Systems of angle supports riveted to the inside of the shell may be used and may suffice amply to support the brickwork when it is built into the furnace, but these narrow ledges cannot in my judgment furnish the sound and substantial support which a body of brickwork two feet or more in thickness receives by resting upon a solid foundation like the mantle.

Moreover the thinness of the inwall seems to have an influence upon the work of the furnace altogether apart from its effect on the durability of the lining. Thin-lined furnaces have been found by their managers to be sensitive to the quantity and temperature of the cooling water circulated over the shell and in general to have troubles to which furnaces with linings of normal thickness are not liable, and some of the best furnace managers in the country who have tried them have told me that they had had enough and were perfectly satisfied in the future to return to the standard lining.

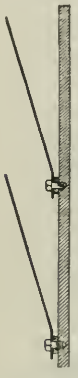

FIG. 12—SPIRAL TROUGH ON WARWICK THIN-LINED FURNACE

Some of the furnaces of the constructions here described are still in operation and some of them are said to be successful, but as a result of several years of experimentation no standard construction appears to have been developed which all advocates of this type of furnace are willing to adopt, and while the advantages of securing permanence of the lines of the furnace as constructed, of requiring for lining purposes only a small amount of brick, and therefore small expense and loss of time in relining, are undoubted, the essentially unsubstantial character of a wall only about a foot thick and 60 ft. or 70 ft. in height leaning inward at the top may well be questioned. Moreover, the thick lining has the advantage that within reasonable limits it gives the furnace some opportunity to cut itself out to the shape at which it will do the best work, so that minor errors of judgment in the original lines of the furnace as built may be corrected by the work of the furnace itself within the thickness of the standard lining, which is not possible with the thin one.

The lines of furnaces are not fixed like the laws of the Medes and Persians but shift with almost every campaign to meet changes of conditions or the changed views of their operators. With a lining of standard thickness and a standard shell large enough to contain it, such changes can within reason be made without affecting the shell, but with the thin-lined furnace this is not true. The shell must virtually have a shape exactly corresponding to that desired for the inside of the furnace and if it becomes necessary to change the latter this involves expensive and time-consuming changes in the shell.

For all these reasons, and for the far better one mentioned above, that in practice the thin-lined construction does not seem to have justified itself, it seems doubtful whether the development in this direction will be extensive or at least very rapid.

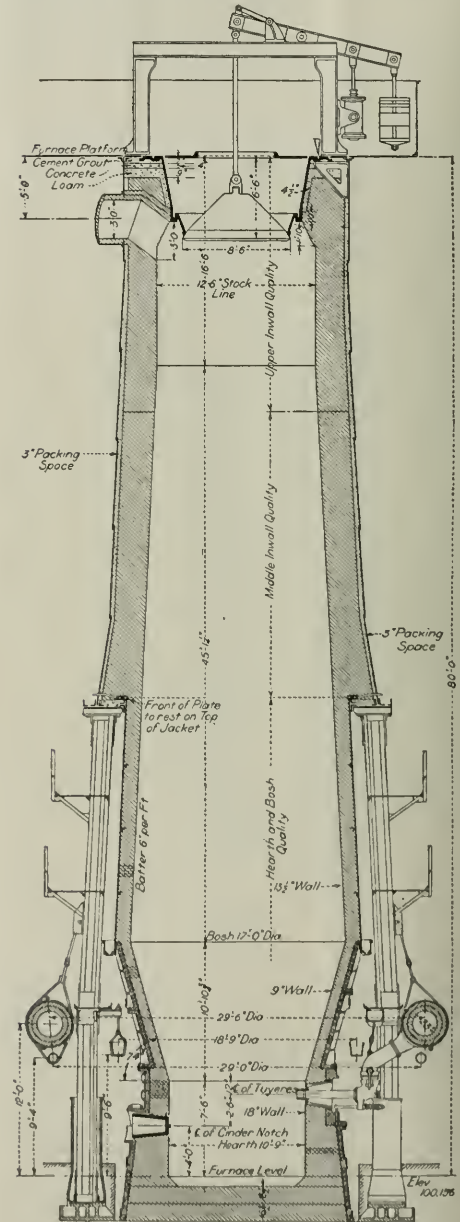

FIG. 13—SECTION OF NORTHERN IRON COMPANY'S PORT HENRY FURNACE

### The Ashland Construction

The construction shown by Figs. 1, 2 and 4 in which the mantle is supported directly upon the tops of the columns, numbering in modern practice from ten to twelve, has virtually been the standard ever since the adoption of the steel-shell construction, but is open to various objections from a practical and operating point of view.

These objections are that the columns come very close to the walls of the bosh and particularly to the outside of the hearth jacket, narrowing up the cooling ditch around the base of the latter and making the removal of any iron which may run into the ditch in a breakout extremely difficult, because this iron locks itself between the hearth jacket and the columns and in some cases can not be removed without blasting which would endanger the columns themselves. Moreover, when this construction is used the bustle pipe carrying the hot blast to the tuyeres has to pass outside the columns and the penstocks, carrying the hot blast from the bustle pipe to the individual tuyeres have to pass between the columns. These penstocks have to be swung out of the way whenever the tuyeres have to be changed, and the columns are greatly in the way at such times. There is nearly always a column close to the tuyere on one side or the other and access to the tuyeres is enormously hindered thereby. These columns interfere with the lead of the individual water pipes from the circular water main beneath the bustle pipe to the tuyeres and cooling plates and make it difficult to determine which cock controls which pipe, a matter of vital importance in case of a partial obstruction to the flow in one of these pipes, which then requires instant attention as the price of preventing the destruction of the cooling member which it supplies and the stopping of the furnace to replace the latter.

The writer having realized for years past the seriousness of these difficulties from an operating point of view when the charcoal furnace at Ashland, Wis., required reconstruction a few years ago, designed it along somewhat different lines, which are shown in Figs. 6 and 14. The central idea of the construction adopted is to remove the columns from their ordinary location immediately under the mantle and set them back far enough out of the way to give complete access to the base of the furnace and to prevent injury to the columns themselves in case of breakouts or other accidents around the furnace.

This was accomplished by building a square frame work of extremely heavy plate girders, the inside distance apart of which was slightly greater than the outside diameter of the shell of the furnace. These girders were supported on the top of the four columns to which they were riveted and strongly braced to prevent the possibility of failure by twisting. The shell was supported on these girders by eight brackets, two on each girder, these brackets being heavily riveted to the shell.

In order to prevent the sagging of the mantle plate eight cantilever brackets projected in under the mantle, one vertically under each of the main brackets. These were supported by a downward extension of the main angles which fastened the main brackets to the shell and the outer ends were held down by struts extending down from the ends of the main brackets.

The construction was a success in all respects and gave a degree of accessibility and convenience in operation around the bottom of the furnace beyond comparison greater than that of any other type. This accessibility is indicated by Fig. 14, which shows two men abreast, standing shoulder to shoulder inside the column, and outside the outermost point of the penstock. Of course, the tuyeres do not come in line with the columns in this construction any more than in the ordinary one.

For a furnace of this size no change in the design of the construction need be made. For a coke furnace of greater size and with greater liability to serious difficulties of operation, it would probably be desirable to use five columns, so that if one of them were to fail three of the girders, encircling more than one-half the furnace, would still stand and support it. This, of course, would only happen in case of a terrific disaster because the columns are set back so far from the furnace that no ordinary one could affect them, and on account of the abundant room around them they can be thoroughly protected by brick work.

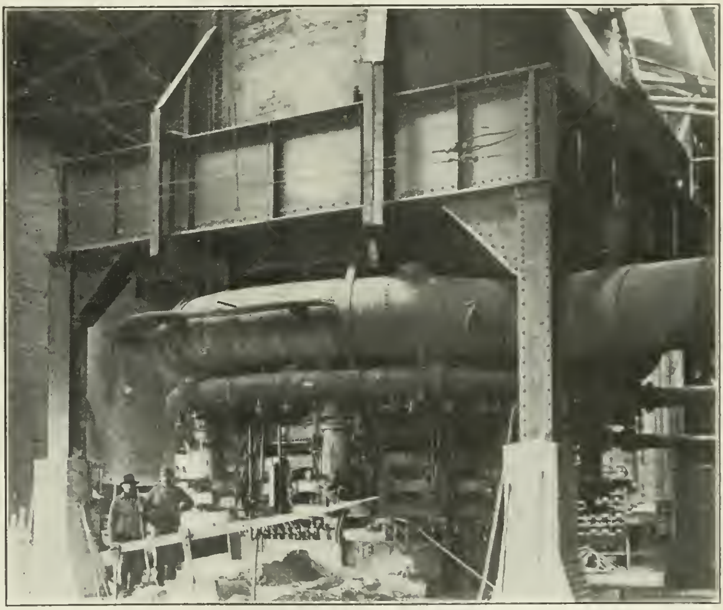

FIG. 14—ASHLAND CONSTRUCTION

In case this construction were used for a coke furnace a box girder would be used instead of the single plate girder and this box girder would be made watertight and serve for the circle pipe to supply cooling water around the furnace. This would prevent any possibility of the girders being softened or affected by heat no matter what happened.

This construction permits the bustle pipe to be put inside of the columns and thus to have the penstocks as close to the tuyeres as may be desirable without having any interference between the penstock and the columns. This also shortens up the bustle pipe materially, which reduces both its weight and its cost. One of the important features of this construction when used to replace the standard type is that the foundations, lying entirely outside those of the old construction may be put in while the latter is being torn out, and the structural work may be erected before the old furnace is down, as was done in the case illustrated, with the saving of many weeks in time, worth many thousand dollars more than the slight additional cost of construction.

### Firebrick

There is scarcely any feature of the construction and operation of the blast furnace of more importance than this and probably none concerning which less is known by the great majority of those to whom it is so important, the furnace managers.

The problem of firebrick has never been solved in terms of chemistry, or if so the solution is not known to furnacemen. This is probably because several other factors, such as the fineness of the grinding of the clay, and the method by which it is molded, the temperature and time during which the bricks have been burned, and other factors not reflected in their analysis have a vital influence on their character.

For this reason firebrick are to a great extent bought and sold on the basis of workmanship, freedom of the bricks from warpage, and general reputation. It is true that iron and alkalies in more than moderate amounts are barred because both unite with the silica at low temperatures and cause the fluxing of the brick under conditions far less severe than can be met with impunity by bricks free from these impurities. But further than this chemistry does not play a heavy rôle in the purchase or sale of firebrick.

It was customary a generation or more ago to use very large bricks, the size of 6 in. square on the small end, by 9 in. or 14 in. long was the standard in certain of the older iron-producing regions. But this was followed by a period in which a thickness of about 2½ in. became standard, virtually the same as that of red brick. These were made in lengths of 9 in. and 13½ in. so that two of one would equal three of the other. The straight, commonly known as the "square" brick, is 13½ in. long, 6 in. wide, or in the case of the tapered or circle brick, known as "keys," 6 in. wide at the larger end. Similarly the straight brick, 9 in. long is 4½ in. wide, and the "keys" 4½ in. wide at the large end.

These are relatively small bricks and require much labor for laying and involve a great number of joints, but it was claimed by some furnace men for many years that thicker bricks could not be burned satisfactorily, though I have seen years ago thousands of brick 6 in. thick which gave complete satisfaction in the furnaces in which they were used, which were small coke furnaces.

In very recent years firebrick manufacturers began to make furnace bricks 3 in. thick, and these are very much freer from warpage in the burning process than the thinner bricks as well as requiring less joints and less labor to lay them. They are, therefore, very much to be preferred from practically all points of view except that of cost.

In this respect the brickmakers have established certain customs which have not been permitted to any other trade. The standard price of bricks is based on the 9-in. by 4½-in. by 2¼-in. brick. Smaller bricks than the 9-in. are charged for at the same rate per brick as if they were the 9-in. size. This is explained by the brick maker on the ground that the clay in the brick amounts to very little but that the workmanship on it is just as much in the small brick as it is on the large one. The 13½-in. bricks, on the other hand, take a price of nearly 20 per cent higher than the 9-in. based on the same volume.

When he is asked why this is so the brick maker replies that they are more difficult to handle and to burn.

Similarly when it comes to the 3-in. lining instead of the standard thickness, the brick maker insists that he must have an increase of about 20 per cent in the price per unit of volume of these, although the warpage in this case is very much less, the labor decidedly less, and the burning but little more, apparently on the ground that he needs it, and he usually succeeds in getting it.

It is, however, no more than fair to the brick manufacturer to say that quality does not always receive the consideration from the furnace man that it should, and the manufacturer of a superior grade of brick is often forced to compete against a poor grade of brick on a piece basis, which is neither fair nor sensible, but is to a large extent the outcome of the difficulty in determining what real quality is, already described.

Firebrick are made in three qualities known respectively as "hearth and bosh," "inwall," and "top," intended for use in those regions of the furnace for which they are named, except that formerly the "hearth and bosh" quality was usually continued a number of feet above the top of the bosh, but in the best recent practice this quality stops at the top of the bosh.

These differences in quality are adapted to meet the difference in conditions in the different portions of the furnace. In the hearth and bosh there is little or no abrasion but intense temperature, and intense scouring action of slag and iron. To meet these conditions the bricks are made with a relatively large proportion of flint clay and a correspondingly smaller proportion of plastic clay. These bricks are not exposed to much abrasion and are therefore not particularly designed to resist, but through their composition and burning are made to stand extensively high temperatures successfully.

In the middle zone of the furnace in which the lining is known as the "inwall" the conditions of temperature and chemical action are considerably less severe, while those of abrasion due to the presence of some of the solid portions of the charge and the sand-blast action of its fine portions at the velocity imparted by the blast are considerable, and the cone in this portion of the furnace being convergent upward the sand blasting action is a factor to be reckoned with, whereas in the bosh with its divergent upward flare this is not the case. Inwall bricks, therefore, are made with more plastic and less flint clay than hearth and bosh brick to meet these conditions. At the same time they still have high heat resisting qualities.

At the top the conditions of abrasion are extreme, as has already been described, while the temperature in good practice in this zone of the furnace is generally below 1000 deg., so that the necessity of refractory character in the lining of this zone can be to a certain extent neglected, or at least need only receive an insignificant amount of attention as compared with what it demands in the lower zones. For this purpose the bricks are made with a large proportion of plastic clay pressed very hard, and burned to a great density, some of them resembling what is known as vitrified paving brick, almost as much as they do firebrick, and for the same purpose, resistance to abrasion.

Where no form of stock line protection is used such as those described above or an equivalent, the quality of the top brick is fully as important as that of the hearth and the bosh brick since top bricks which do not resist abrasion, permit the stock line to be gouged out by the drop of the stock from the bell, with the result that the correct distribution of the stock is made impossible and becomes largely haphazard, which is necessarily followed by extremely bad operation in the lower portion of the furnace, with the result of poor quality of iron, high fuel consumption, or of both. The necessity of repairing the stock line has for this reason been responsible for an appreciable percentage of all the cases in which blowing out for repairs have been necessary, though the fact may not have been apparent in all cases, because when a furnace which has been working well gradually begins working worse and worse, it is commonly and in general rightly assumed that the lining is too far gone to permit it to do further good work, and without any analysis as to the location of the wear which is responsible for the bad work, it is generally attributed to the inwall, although the top may be the part to blame.

It is unfortunate that more exact and accurate knowledge is not at hand on the subject of firebrick and their suitability for lining purposes, but the problem is so complicated that a complete analysis would be possible only after years of experience by an organization which contained both an experienced firebrick maker and experienced furnace men, a condition which has seldom if ever existed.

The firebrick manufacturer has, therefore, to adapt his product to the conditions described by the furnace man, and the furnace man has to use the brick furnished to him by the brick maker in the prayerful hope that they will give the results desired, but in the vast majority of cases without any better foundation for this hope than his confidence in a given brand of brick, and perhaps his belief that a certain brick maker understands the conditions well enough to provide him with a suitable lining.

It is greatly to be desired that the furnace man and brick manufacturer should meet directly rather than through their respective selling and purchasing agents. By discussing frankly and without prejudice their respective objects and difficulties progress would be made in real knowledge of this subject with resultant benefit to both.

I have already described the enormous change in the furnace conditions which began in the middle nineties. The greatly increased outputs and the vast increase in percentage of fine ore used in the burden, in combination with the introduction of mechanical charging brought about conditions under which the lining problem seemed to be almost insoluble. I know on the best authority that one of the largest brick makers was desperate at one time over the situation and would have been glad had he felt that he could afford to do so to surrender the furnace-lining portion of his business.

It seems extremely likely from the information which has been developed within recent years in connection with methods of charging, that these have been more responsible for unsatisfactory life of linings than was the poor quality of the linings themselves in many cases in which the firebrick manufacturer had to take the blame.

It has long been known that bad filling would rapidly destroy a lining by channeling, but certain types of mechanical charging which are theoretically correct produce conditions in practice under which it would be impossible for any lining to survive for any considerable length of time.

This matter really belongs under the subject of stock distribution and will be treated at greater length in an article on that subject.

### THE LAYING OF THE FIREBRICK

The mortar used for this purpose consists of ground fireclay which is mixed to grout of a consistency to suit the ideas of the furnace man or the boss bricklayer, and usually kept hot during the mixing and to a considerable extent even during laying, by a steam coil in the bottom of the clay box.

This grout or mortar is generally mixed quite thin, poured onto the brickwork with a large dipper and flushed into the joints of the brickwork, both from below by sliding the brick being laid up against the one just laid, so as to fill the joint as nearly as possible with fireclay, and then from above by filling in the space and working the fireclay down between the two bricks with a trowel if any opening sufficient for that purpose exists, which in general it should not do.

Many of the difficulties with linings have been attributed by some furnace men to bad bricklaying and particularly to wide joints. Some go so far as to insist that all unevenness must be removed from the bricks by chipping each individual brick where any appreciable amount of warpage exists, producing what is known as a case-knife job. This means that every joint shall be laid so close that it is impossible to get the point of a table knife into it.

Thick joints are undoubtedly very bad, but I have never seen any results produced by such extreme precautions which seem to me to justify the very greatly increased expense in laying the lining by this method. Careless work should on no account be tolerated, and if joints are found which are not thoroughly flushed the brickwork should be torn down and rebuilt properly. But as long as the firebricks themselves are made of clay suitably burnt, it has never been evident to me why the clay in the joints should not be burnt practically into the same structure as the brick itself, and in fact the brickwork which is torn out during the relining periods from the lower portion of the furnace where the heats have been high come out in blocks, the line of whose breakage frequently pays little or no attention to the original joints in the brickwork, proving to my mind that when properly laid, the fireclay joint becomes, by the action of the furnace itself, almost as good as the brickwork.

This statement is, of course, predicated on the assumption that fireclay of the same quality as the brick will be used. If inferior clay be substituted it may act as flux for the brick themselves and absolutely destroy the lining.

The practice of making the fireclay thin may easily, in my judgment, be overdone, for the reason that if the clay is very thin, when the bricks are settled to place with a mallet, if there is the least particle of warpage, the brick springs enough to throw the thin clay out of the joint and when it springs back to shape again this joint is practically open. When the fireclay is made so thick, on the other hand, that it will just about pour from the dipper, it is too plastic to permit this action and while the bricks may be driven up to a solid bearing with one another the slight joint which remains after they are in contact is fairly filled with fireclay.

### THE FILLING OF THE PACKING SPACE

In former times when furnace shells were built not much more than a quarter as strong as they are to-day they were frequently burst by the expansion of the brickwork within them and it was therefore universal practice at one time to provide a space of 3 in. to 6 in. between the outside of the brickwork and the inside of the shell which was filled with some yielding material to allow for the expansion of the brickwork, and yet continually resist it. In modern practice shells are so strong that they can resist the expansion of the brickwork and the latter is therefore laid up close to the shell and the small space necessary as a construction allowance is quite frequently grouted with concrete which, of course, is entirely unyielding. This means that the shell must be strong enough to resist the expansion of the brick or else it must stretch enough to accommodate the expansion of the brick within its elastic limit. Probably both these actions take place to some degree, but in any event this plan is not safe except with a shell of the strongest and best construction. If the brickwork were laid up tight inside a shell of older type the latter would probably be burst within a short time, as unfortunately has happened only too often even with the greatest precautions.

To prevent this it is customary with such shells to leave a space between shell and lining and fill it with some material which is yielding and yet to some extent resistant. The necessity of resistance arises because if an open space were left between the brickwork and the shell the internal pressure would push the brick back, break the bond, and ruin the keying, so that some bricks would be likely to fall out which would start a hole in the lining, and once started this would rapidly enlarge itself so as to destroy the lining. The bricks therefore must be held up to their work by some sort of filling between them and the shell.

Some furnace men prefer for this purpose clay, but clay is only slightly compressible, and I prefer pumice cinder, made by running a light slag onto wet ground, or into a tank of water. The steam formed by the heat of the slag puffs the latter up into a huge sponge whose total volume is many times the volume of the slag from which it is made. As it is crushed under pressure its volume becomes smaller and smaller by the progressive destruction of the cells, first of the larger and then of the smaller sizes, but the material maintains its resistance to compression almost constant throughout a very great diminution of volume.

These are the conditions which we have to meet, as brickwork, unless rigidly bound, does not expand elastically like steel, but when expanded retains its new size, never contracting, or never to anything like the degree to which it had previously expanded, so that as its temperature varies it undergoes a slow but constant growth. Thus a furnace shell may be amply large at the beginning of a campaign and for several months or a year, but gradually as the lining increases in size, when all the compressibility of the backing is gone, the direct expansionary force of the bricks is transmitted to the shell, and while the steel is stronger than the brickwork inch for inch, the latter is so much greater in area in any given section of the furnace that it generally bursts a thin shell when the "give" of the backing is gone.

In order to make the backing gas-tight the pumice cinder is sometimes mixed with clay, but this has the effect of reducing its compressibility especially as the clay is apt to burn hard after the furnace has been in operation for a while, and this therefore limits the amount of compression which a given portion of the backing can undergo without exerting undue stress upon the shell.

### DRYING THE LINING

Even with the best possible practice several tons of fireclay are used in laying the lining of a furnace, and this being mixed with something like an equal weight of water there is a great quantity of water in the lining when the brick laying is finished. This is capable of doing great damage and should therefore be removed by thoroughly drying the lining before the furnace is put into operation.

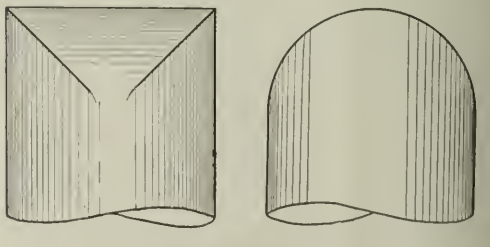
Various methods are in use for this but usually a temporary brick oven is built immediately in front of the tapping hole, and communicating with the furnace through it. The bell is closed and draft produced either by opening the bleeder or allowing the main draft stack to draw on the furance through a stove. A fire is built in the temporary oven and the gas from this passes into the furnace and warms it up, drawing out the moisture from the face of the brickwork first, and gradually as the heat works through drying out the whole mass quite completely.

The hot gas also acts as a carrier for the steam formed from the moisture and takes it out of the furnace. This drying-out process lasts anywhere from one to three weeks according to my judgment of the furnace manager and the state of the iron market.

There is no doubt that the operation is much better carried on slowly than rapidly, but a very moderate rate of firing will bring the warmth through a wall of 2 ft. or 3 ft. thickness in the course of three or four days, and a week of this treatment is in general sufficient to dry out the clay about as thoroughly as it can be done by this method. Of course, if the furnace is ready for operating before the rest of the plant it is well worth while to continue the fire for drying out for two or three weeks or even longer if convenient. But in my judgment three-fourths of all the benefits to be obtained by drying will be obtained in the first week of moderate but steady firing, day and night.

The removal of this moisture not only prevents the possibility that the rapid heating which would come from the actual operation of the furnace on a green lining would convert the moisture of the fireclay into steam so fast as to drive the clay out of the joints, and perhaps blow objectionable holes through the packing at the back, but it also exercises a very objectionable effect on the operation of the furnace while blowing in when it is already very cold by reason of the fact that its initial charge is not preheated in its descent, but necessarily cold clear to the bottom.

I have never had any experience with blowing in on a green lining, but I should expect that much more fuel would be required for the first two or three days of such blow in than would be required on a furnace with a thoroughly dried and warmed lining, and that the difficulty and delay in getting the furnace into normal operation fould be much greater.



CYLINDRICAL STOVE TOP

**Erratum.**—In our last issue, page 408, Fig. 35 of a cylindrical stove top was incorrect due to a mistake of the draftsman. It is now reproduced in correct form. In the early days many stoves were fitted with a cylindrical top as shown in this illustration and this shape conforms with the mechanical requirements that all sections of the stove shall be circular in order to resist deformation, but this style of top is difficult and expensive to fit and seems particularly liable to give out along the square corner where the horizontal cylindrical surface of the top meets the vertical surface of the stove body, and stoves are now almost universally fitted with either conical or spherical tops.

# Notes and Observations on Ore-Treatment at Cobalt, Ontario, Canada—II.

BY H. C. PARMELEE

### Concentration

In a preceding article[1] the writer pointed out the growing importance of concentration at Cobalt, and showed that by far the greater tonnage of ore mined is treated first by ore-dressing processes. The material thus treated is low-grade wall rock, containing from 15 to 30 oz. silver per ton. It is distinguished from the high-grade ore which occurs in narrow veins and contains from 2000 to 4000 oz., and even as high as 6000 oz., silver per ton. The value of the low-grade ore depends on the extent to which the vein walls are mineralized. As delivered to the mill it is enriched by the admixture of fine ore broken from the high-grade veins. Mill feed in the district will range from 20 to 35 oz. silver per ton.

By preliminary processes of hand-sorting, either underground or on picking-belts, and coarse crushing and jigging, the high-grade vein material is readily recovered. The wall rock, on the other hand, in which silver and its minerals are disseminated, requires fine crushing before concentration can commence.

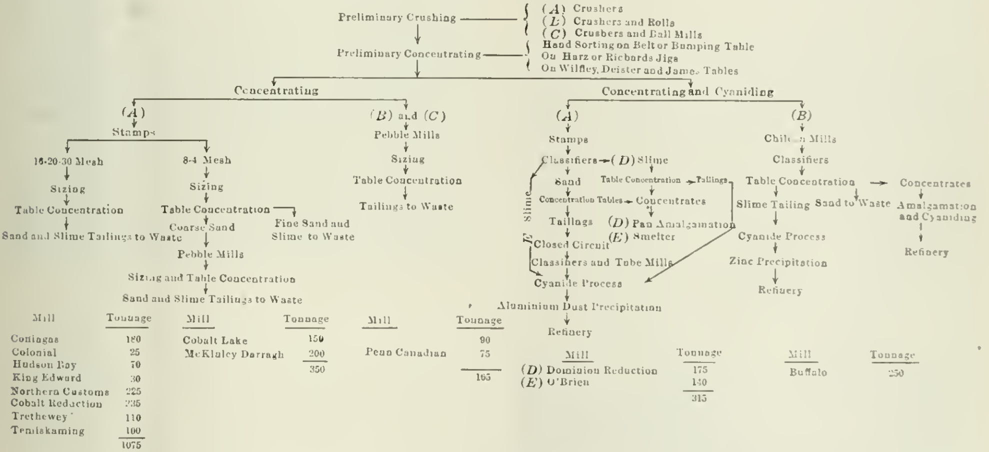


FIG. 1—COMPARATIVE FLOW SHEET OF COBALT CONCENTRATORS (FROM DATA COMPILED BY FRAZER D. REID)

Excepting the friability of the various silver minerals, the low-grade ore presents no serious difficulties in concentration. The effect of an increased proportion of these minerals in the ore is to raise the grade of slime tailing, and consequently increase the loss unless this product is cyanided. Thus, at one of the mills where cyanidation of slime tailing is practiced, when the concentrator was treating a 40-oz. ore the slime tailing carried as much as 60 oz. per ton, but when the grade of mill feed dropped to 20 oz. the slime was reduced to about 8 oz.

The ratio of concentration varies at the different mills, but is high. An average probably would give between 45:1 and 50:1, with an extreme range of 25:1 and 100:1.

A comparative flow sheet of Cobalt concentrators, including those at which cyanidation also forms a part of the treatment, is given in Fig. 1. This is compiled from data contributed by Mr. Fraser D. Reid, superintendent of the Coniagas mill, and is abridged from a more extended flow sheet published by him.[2] This shows at a glance several features which impress the visitor at Cobalt mills: (1) the general use of stamps, and (2) the lack of stage crushing and concentrating.

### Crushing and Grinding

The use of stamps or rolls on Cobalt ore is a point of controversy among millmen in the district, although generally the seal of approval is placed on stamps if we may judge by their more extended use. Fig. 1 shows that stamps are used for the crushing of slightly over 80 per cent of the total tonnage concentrated. An objection to stamps is the quantity of slime and fine sand produced, amounting to 30 or 40 per cent of minus 200-mesh pulp when crushing through 16 to 30-mesh screen. This objection is emphasized in those cases where no regrinding is practiced, and where fine screens are used on the batteries to insure original grinding to the requisite degree of fineness. It is claimed that rolls will make not more than half the amount of fine produced by stamps. The Chilean mill also slimes less than stamps: thus, a feed of —6 + 12 mesh material ground in a Chilean mill through 12-mesh screen gave only 6 per cent minus 200-mesh.

The advocates of stamps claim that rolls are inefficient machines in crushing the tough conglomerate; and even some of those who favor rolls, when condition of product alone is considered, admit that rolls do not stand up to the work and that crushing cost is increased by their use. At the same time it is probable that large heavy rolls have not been given a trial. Another argument in favor of stamps is that the ore can be ground in them to the requisite degree of fineness in one operation, thereby eliminating regrinding machinery. This leads, of course, directly to a related point on which also there is a difference of opinion.

### Stage Grinding and Concentrating

To anyone who is familiar with general concentration practice on base-metal ores, such as occur in the western United States, the absence of stage reduction and concentration in most Cobalt mills will be a matter of surprise. The general tendency is to crush in one operation to a degree of fineness which experience shows will liberate most of the valuable metal and minerals. There are exceptions, notably the McKinley-Darragh and Cobalt Lake mills, wherein the crushing is done in stages by successive machines, with intermediate classification and concentration.

[1] This journal, July, 1914.

[2] Milling Practice in Cobalt, by Fraser D. Reid, *Bulletin*, Can. Min. Inst., May, 1914.

It is true,. as already pointed out in our last issue, that all of the silver in these ores will not be released from gangue save by very fine grinding, and the millman must determine the economic limit of crushing. This seems to have been found between 16 and 30 mesh at different mills. Those who advocate single-stage crushing maintain that by grinding to, say 20 mesh and concentrating, a 16 to 20-oz. ore will yield a tailing carrying only 3 to 4 oz. silver per ton. To make a further recovery from this tailing would require very fine grinding which would not be profitable. In support of this view, Mr. Reid gives the following screen analysis of a tailing obtained from such treatment, showing the uniform silver content of the different grades down to minus 200 mesh, where there is a sudden increase.[3]

Screen Analysis of Sand Tailing from 16-Mesh Battery Discharge

| Mesh | Per Cent Weight | Oz. Silver per Ton | Per Cent Value |
|---|---|---|---|
| + 30 | 22.1 | 3.2 | 22.6 |
| + 60 | 31.8 | 3.0 | 30.3 |
| + 100 | 28.6 | 3.0 | 27.4 |
| + 200 | 13.1 | 2.5 | 10.5 |
| — 200 | 4.4 | 6.5 | 9.2 |

Opposed to single-stage grinding are those who feel that the concentrating practice can be improved by crushing in several stages, with suitable classification and concentration at each step. While the advocates of this procedure are in the minority, they feel that progress in concentration in the district should be along this line and that future economic conditions will demand a change in this direction. Perhaps a suitable line of crushing and grinding machinery for this work would be gyratory and jaw breakers, large heavy rolls, disc grinders and pebble mills.

A new tube mill liner, known as the Globe, is being used at the McKinley-Darragh mill and is regarded favorably. Like the El Oro it consists of metal ribs with spaces in which the pebbles become wedged, but the ribs extend around the inner face of the tube instead of lengthwise. This liner is being used also at the Hollinger mill in the Porcupine district.

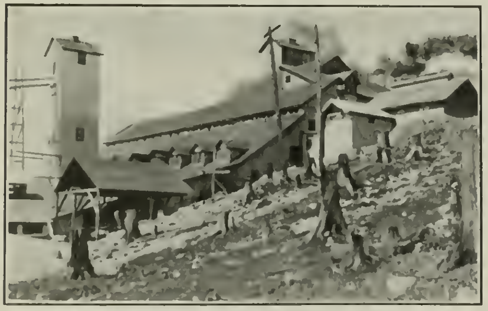

FIG. 2—CONIAGAS MILL, COBALT

With regard to classification, it may be said that it is not practiced to the degree considered advisable and essential elsewhere. Perhaps the high specific gravity of the concentrate makes this necessary, but it is certain that more extensive classification is now being adopted in some plants, and the operators of those mills feel that the change is showing an improvement in results.

Harz and Richards jigs are used for coarse concentration, but the former predominate. They are relied upon to recover silver nuggets and high-grade ore, which ordinarily are removed by skimming the jig beds. Wilfley, Deister and James tables are found throughout the district, the two latter being in favor and exceeding the first in number.

### The Coniagas Mill

One of the typical concentrators of the district is the Coniagas, a view of which is given in Fig. 2. The ore is crushed in stamps, classified and concentrated, the tailings going to waste. Average mill feed contains 34 oz. silver per ton; sand tailing, 3 to 4 oz., and slime tailing, 6 to 7 oz. Preliminary treatment ahead of stamps results in cutting the grade of original feed in half, so that the stamp discharge contains about 16 oz. silver per ton. Concentrates are shipped to the company's smelter at Thorold, Ont. A flow sheet of the mill is outlined in Fig. 3.

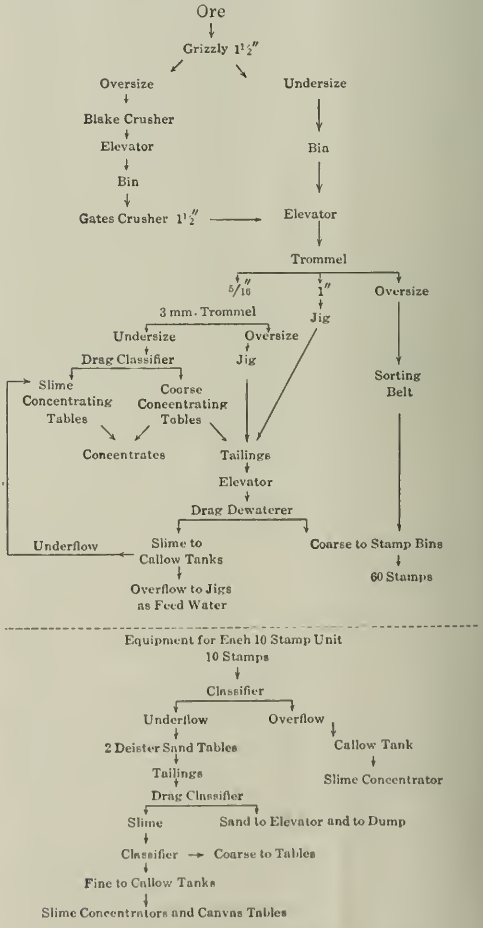

FIG. 3—FLOW SHEET, CONIAGAS MILL, COBALT

Manganese and chrome steels are used in crushing and grinding machines and wherever apparatus is subjected to excessive abrasion by the ore. Jaws and cheek-plates on Blake crushers, and concaves and mantles on gyratories are manganese steel. The same metal is used for buckets on dry and wet elevators. Buckets on dry elevators have been in service for three years, handling 180 tons of ore per day, and probably are good for the remaining life of the mine. On wet elevators these buckets have lasted for 15 months and probably will show a life of two years. Trommels also are of manganese steel, as are the mortar liners. The latter are 1 inch thick and sectionalized so that the part most subject to wear can be reversed and then replaced without discarding the entire plate. This practice has resulted in doubling the life of the liners.

### Tailings Disposal

The Coniagas mill is so situated that sand tailings have to be stacked. As shown in the flow sheet the sand and slime are separated by a drag classifier, the slime being concentrated further and the sand sent to the tailing elevator, which is shown at the left in Fig. 2. Sand is discharged from the elevator into a launder with the minimum amount of water required for transportation and flows to the point of discharge where it stacks as shown in Fig. 4. The cost of this method of stacking is 0.7 cent per ton. A sample of the tailing is cut out at the elevator discharge and returned to a pilot table in the mill, where the attendant is able to observe the presence of any metal or mineral that may be going out of the mill due to faulty operation.

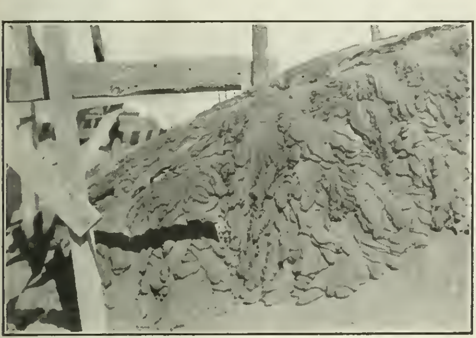

FIG. 4—SAND TAILINGS STACKED AT CONIAGAS MILL

Another system of stacking sand tailing, by aerial tramway, is shown in Fig. 5. This is the method adopted at the Buffalo mill. The sand is dewatered in the mill by a drag conveyor which discharges into a bin from which the tram buckets are loaded. There are two buckets attached to the running cable, one being at the loading station while the other is dumping. The buckets dump automatically and the sand is sluiced down the launder by water conducted to the dump through a pipe shown in the view.

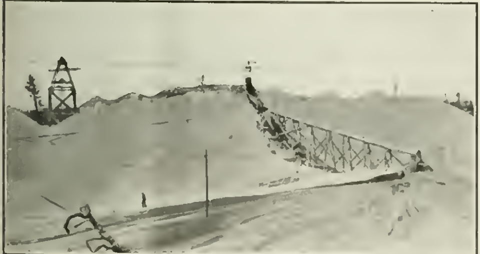

FIG. 5—STACKING SAND TAILINGS AT BUFFALO MILL, COBALT

### The Trethewey Mill

In Fig. 6 the treatment given at the Trethewey mill is outlined in considerable detail. This plant comes within the same classification as the Coniagas, stamps being used for crushing, followed by simple classification and concentration on sand and slime tables. There is no regrinding. At one time a Huntington mill was used as a regrinder, but it was abandoned as being wholly unsuited to the work of grinding such tough ore. James and Deister tables are used, and a Deister-Reid slime table recently has been added. This latter is a modification of the Deister slime table by Mr. Reid, superintendent of the Coniagas mill, and is finding considerable favor in the district.

FIG. 6—FLOW SHEET, TRETHEWEY SILVER COBALT MINE, LIMITED

A successful device for removing chips of wood from the ore before it passes to the stamps is in use at this mill. It is placed at the drag dewaterer which receives the jig tailings. It consists of a series of brushes mounted on a belt traveling across the trough of the dewaterer at right angles to the travel of the drag. The brushes dip beneath the surface of the water, engage the floating chips and remove them at one side. The device has been of great assistance in avoiding the blinding of battery screens and preventing the accumulation of fine wood pulp in the concentration system.

### Cost of Concentration

Mr. Reid gives the cost of concentration at the Coniagas mill as $1.32 per ton of ore treated.[*] This excludes the cost of coarse crushing and preliminary concentration, and refers only to the work done at and beyond the stamps. It includes, however, allowances for depreciation, interest on investment, insurance, etc. At another mill the cost of all work, including coarse crushing and concentration, is given as $2.67 per ton. Details of various concentrating mill costs given by Mr. Reid are shown below.

### Cyanidation of Cobalt Ores

It can be readily understood that the proposal to reduce the complex ores of Cobalt by the cyanide process was received with skepticism. Consequently the successful application of this method may be regarded as a triumph in hydrometallurgy, as pointed out by Mr. Clevenger in our recent symposium on the complex-ore problem.[5] Containing, as they do, combinations of silver, arsenic, sulphur, antimony, cobalt and nickel, these ores do not appear attractive to the cyanide metallurgist, and it is not surprising that concentration and smelting have formed the predominating basis of treatment. Advocates of the latter system claim an advantage on low-grade ore, where the stamp discharge carries from 12 to 15 oz. silver per ton after about an equal amount has been removed by preliminary coarse crushing, sorting and jigging. Possibly the margin of profit in favor of either process is narrow in any event, but when the Nipissing company contemplated the erection of a low-grade mill for the treatment of, say 30-oz. ore, and considered the merits of concentrating and cyaniding, the latter process was adopted. Preliminary estimates showed a profit of $1.59 per ton in favor of cyaniding,[6] and the results since obtained in practice have more than confirmed these estimates. Certainly the advantage gained by a quick conversion of ore into marketable bullion is a considerable benefit offered by cyaniding as compared with concentrating and smelting.

Excluding those mills at which slime tailing from concentration only is cyanided, there are others in which cyanidation, with and without amalgamation, is the reduction process employed. At the Dominion Reduction and Buffalo mills the ore is first concentrated, after which the slime tailings are cyanided and the concentrates treated by a process of cyanide-amalgamation. At the Nipissing high-grade mill[7] cyanide-amalgamation is employed, while at the same company's low-grade mill cyanidation only is used. The process of cyanide-amalgamation in use at the Buffalo is the same as that first used at the Nipissing high-grade mill.

### The Nipissing Mills

The Nipissing Mining Company operates two mills: one for high-grade ore, which has been in operation since February, 1911, and the other for low-grade ore, which went into commission in November, 1912. Since the construction of the latter mill all ore is received at a central washing and sorting plant, where the rich ore is selected and sent to the high-grade mill, the balance going to the low-grade plant. The washing plant and low-grade mill are situated on Nipissing hill, across Cobalt lake from the town of Cobalt. A view of this mill, as seen from the town, is shown in Fig. 7. The high-grade mill is shown in Fig. 8, and a flowsheet is given in Fig. 9 showing the relation of the two plants.

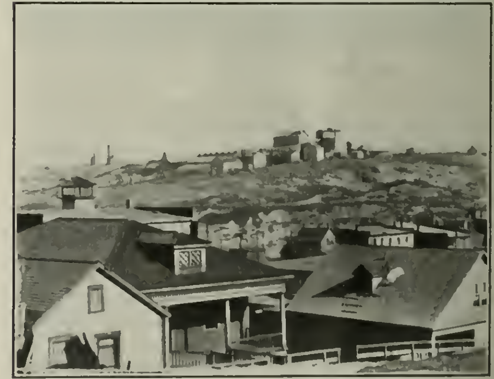

FIG. 7—NIPISSING LOW-GRADE MILL, FROM TOWN OF COBALT

### Washing and Sorting Plant

Run-of-mine ore contains, on an average, 50 to 55 oz. silver per ton. It is crushed to 3-in. size before delivery to the bins of the washing plant, where it is drawn into cars and weighed on registering scales that give an accurate record of all ore received from the mines. In the succeeding operations the ore is washed, sized, hand-picked and jigged for the removal of the high-

[7] Nipissing High-Grade Ore Mill, Cobalt, by R. B. Watson, *Eng. & Min Jnl.*, Dec 7, 1912

grade portion, containing about 2500 oz. silver per ton, which is sent to the high-grade mill. The jigs handle two sizes of ore, one between 0.5 and 1.5 in., and the other between 3 mm. and 0.5 in. The discarded low-grade ore coarser than 1.5 in. is crushed to that size before going to the battery bins; the balance, including jig tailings, is sized through 3-mesh screen, the oversize going to battery bins and the undersize to the tube mills. In this way the batteries are relieved of handling about 10 per cent of the ore which is already crushed fine enough for tube mill feed.

FIG. 8—NIPISSING HIGH-GRADE MILL, COBALT

### Cyanide-Amalgamation of High-Grade Ore

In 1913 the high-grade mill treated 1832 tons of ore containing 4,804,928 oz. silver, of which 1200 tons was Nipissing ore averaging 2501 oz. per ton. The tonnage treated at the high-grade mill is between 1½ and 2 per cent of the total ore mined and sent to the washing plant. The recovery is 99 per cent, of which 97 per cent is by amalgamation and 2 per cent by cyanidation.

The main step in the process, which was devised by Charles Butters and G. Howell Clevenger, consists in grinding the ore for 10 hours in a tube mill with mercury and strong cyanide solution. The ore is first crushed to 20-mesh size. A tube mill charge depends somewhat on the grade of the ore, but consists in round numbers of about 3 tons of ore, 4 tons of mercury, 1½ tons of 5 per cent cyanide solution and 6 tons of pebbles. The tube mill is of special construction and is adapted to receive compressed air to aid in cyanidation. Fine grinding is necessary to liberate all of the silver, and at the end of the operation practically all of the pulp will pass a 200-mesh screen.

The tube is charged and discharged through manholes. When the pulp is ready to be discharged the manhole covers are replaced by screens through which the pulp and amalgam flow into a settling tank. Amalgam and mercury are drawn from the settler into a clean-up pan and then into canvas filters, and the amalgam is finally retorted.

The ore residue is given a further treatment by agitation in cyanide solution, followed by decantation and vacuum filtration. The solution is precipitated by zinc shavings in the usual manner. An unusual sight is presented in the zinc boxes owing to the change of color of the solution as it flows from upper to lower compartments. The head solution is clear and colorless, but it gradually acquires a reddish tint and exhibits a marked coloration in the last box. This is due to the presence of nickel in solution and probably results from the reduction of nickel cyanide by zinc. When this colored solution is again oxidized by aeration it resumes a normal appearance.

### Recovery of Cobalt Residue and Silver Bullion

The filter residue contains mainly cobalt and nickel minerals, some silver and mercury. The total consumption of mercury in the entire operation of producing bullion is about 20 lb. per ton of high-grade ore, of which about 12 lb. remains in the residue. The balance is lost in volatilization and handling. The residue carries also 20 to 40 oz. silver per ton, 8 to 10 per cent cobalt, 4 to 6 per cent nickel and 30 to 40 per cent arsenic. It is sold to manufacturers of cobalt products, who pay for the cobalt and 85 per cent of the silver. In 1913 the company sold 1659 tons of residue, netting $62,484.

Retorted amalgam and zinc precipitate are melted in a reverberatory furnace and oxidized with air to slag off impurities. The resulting bullion is 999 fine. A small blast furnace is used periodically to smelt reverberatory skimmings and flue dust, and the resulting bullion is further refined in the reverberatory furnace. A baghouse has recently been constructed to recover dust and fume from the blast, reverberatory and retort furnaces, thus adding another refinement to a process which yields a commercially complete recovery of silver from a complex high-grade ore.

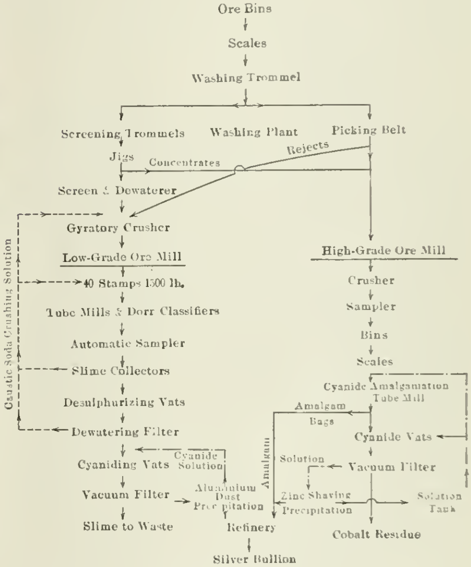

FIG. 9—FLOW SHEET, NIPISSING MILLS, COBALT

Interesting and successful as the Nipissing high-grade mill has been, it is possible that the process may be supplanted by direct cyanidation. Research, which has been such a prominent feature of Nipissing metallurgy in the past, is constantly under way and is now being directed toward the evolution of a scheme to treat high-grade ore and concentrate by cyanidation. Preliminary laboratory experiments have been sufficiently encouraging to warrant proceeding with tests on a larger scale, which are now under way.

### Direct Cyanidation of Low-Grade Ores

The low-grade ore rejected at the washing and sorting plant is treated by the cyanide process as outlined in Fig. 9. The principal features are (1) a wet desulphurizing process which liberates silver from its mineral combinations and renders it soluble in cyanide solution; (2) precipitation of silver with aluminium dust, and (3) the recovery of about 92 per cent of the silver from a 30-oz. ore, in the form of bullion 997 fine. Briefly, the process consists in grinding to slime in caustic soda solution; desulphurizing by contact with aluminium; filtering to remove caustic soda solution; treating with cyanide to dissolve silver; filtering and precipitating the solution with aluminium dust; melting and refining the precipitate.

The milling plant is a model of excellence in design, construction and arrangement, and shows the value of good preliminary engineering. The arrangement of machinery and the relation of the several departments show a freedom from complications which are so apparent in many poorly designed mills. Here even the casual visitor may quickly gain an idea of the system of treatment. All machines are readily accessible for inspection and repairs, and cleanliness is evident throughout. In short, it is apparent that Nipissing ideals are comprehensive and extend to every department of the work.

### Extremely Fine Grinding Necessary

The ore is ground in 0.25 per cent. caustic soda solution, with 5 lb. of lime per ton of ore added at the battery bins to aid in slime settlement. The equipment for this part of the treatment consists of forty 1500-lb. stamps, four 6 ft. by 20 ft. tube mills and seven duplex Dorr classifiers. In order to secure a good extraction by cyaniding it is necessary to grind the ore extremely fine—practically all minus 200-mesh. For this reason the capacity of tube mills and classifiers is unusually large when compared with stamp capacity.

The battery discharge, 7 parts of solution to 1 of ore, is distributed to four of the Dorr classifiers. These machines have higher overflow weirs than usual to prevent the discharge of fine sand; they are also about 5 ft. longer than standard machines and have bevel-gear drives. The slime overflow passes to collecting tanks, and the sand discharge is delivered to the two coarse-grinding tube mills and ground with 40 per cent of solution. The tubes, in turn, discharge to three more Dorr classifiers, the slime overflow from which passes to collecting tanks, while the fine sand is delivered to the two fine-grinding tube mills which discharge back to the set of three Dorr classifiers. Thus the sand is kept in a closed grinding and classifying circuit until it is ground fine enough to overflow the weirs of the classifiers.

### Desulphurizing with Aluminium

The ore ground in caustic soda solution is collected in tanks and allowed to settle. The excess solution is collected in overflow launders and through decanters until the remaining pulp consists of about 1½ parts solution and 1 of slime. It is then ready for the desulphurizing treatment, which decomposes the refractory minerals that contain part of the silver in the ore. Most of the silver is in the metallic state, but some is combined. Thus in a 30-oz. head sample, approximately 80 per cent of the value may be present as metallic silver and 20 per cent in mineral combinations.

The desulphurizing process is the result of research by J. J. Denny of the Nipissing staff.[8] His explanation of the decomposition of silver sulphide by the treatment with aluminium in alkali solution is represented in the following equations.

$$2Al + 2NaOH + 2H_2O = Na_2Al_2O_4 + 6H$$
$$6H + 3Ag_2S + 6NaOH = 3Na_2S + 6H_2O + 6Ag$$

Similar reactions occur with sulphantimonides and sulpharsenides. These reactions are brought about by grinding the thickened alkaline pulp in a 4 ft. by 25 ft. tube mill, lined with aluminium and carrying a load of about 4000 lb. of broken aluminium ingots. This is followed by mechanical agitation in vats lined with sheets of aluminium. At the end of 24 hours' agitation the pulp is filtered, discharged with about 26 per cent solution and treated by cyanidation.

### Cyanide Treatment

Solution of silver is accomplished by 48 to 60-hr. agitation of a pulp consisting of 2 parts 0.25 per cent cyanide solution and 1 of dry slime. The agitation vats have mechanical stirrers and air lifts which are kept in constant operation. The air lift is placed near the periphery of the vat and has two discharge openings one above the other pointing in opposite directions. The combined effect of mechanical stirrer and air lift is a very thorough mixture and agitation of the pulp. After agitation the charge is allowed to settle. Clear solution is decanted and the remaining pulp is stored in tanks where it is kept in agitation until drawn to the filter.

Both alkali and cyanide filters are of the Butters stationary type and are equipped with the latest form of Butters vacuum filter leaf.[9] The cake is dislodged by the application of water from a pipe extending along the top on the outside of each leaf, and no reverse internal pressure is applied. The cyanide filter has 80 leaves and handles charges of 35 to 40 tons in about three hours. The cake is discharged with 26 per cent moisture. The adoption of the new filter leaf has resulted in a number of benefits. The cost of filtration is reduced, filters require less attention, and the fabric lasts longer. Ten-ounce duck is now used, which stands the acid treatment better than the lighter fabric formerly employed.

### Precipitation by Aluminium Dust

Although zinc dust precipitation was a part of the process as originally planned, it was abandoned because experimental work, showed a rapid fouling of solution and loss of dissolving power. Further tests with aluminium dust finally led to the adoption of that precipitant with beneficial results. It was found that mill solution did not become foul, and that it was even more active than freshly prepared solution in dissolving silver. Other benefits obtained in practical operation are (1) the regeneration of 1 2/3 lb. cyanide per ton of ore treated, and (2) the recovery of a silver precipitate carrying about 27,000 oz. per ton. The subsequent melting and refining of this precipitate yields bullion 997 to 999 fine.

There is a tendency for soluble sulphides to form and accumulate in the barren solution. In order to oxidize these sulphides, the barren solution is aerated by means of air lifts before it is used again. His investigations on this point lead Mr. Denny to believe that soluble sulphides form as a result of the reduction of thiosulphates by aluminium in alkaline solution. If these sulphides were not oxidized in some manner they would tend to form potassium sulphocyanide, and this salt, Mr. Denny points out, is not convertible into soluble sulphide by aluminium and caustic soda except under conditions of concentration that do not obtain in mill solutions.

Aluminium does not accumulate in solution as some have surmised, but remains constant at about 0.08 per cent to 0.1 per cent, as in the case of zinc. Accumulation is prevented by precipitation of the aluminium as calcium aluminate during the cyanide operation, and this passes out of the mill with the filter residue. It will be recalled that the battery pulp is charged with lime to aid in settlement, and that the residue from the dewatering filter still carries 26 per cent of the original alkaline solution with its quota of lime. When cyanide solution carrying some aluminium is added to this pulp the reaction between lime and aluminium occurs.

---

[9] This leaf was described in this Journal Jan., 1914, p. 65, and a similar leaf was referred to in our issue for July, 1911, p. 479. Recent patents relating to Butters slime filtration are numbered 1,078,991, 1,096,132, 1,100,217-18-19-20-21-22-23-67.

$$Na_2Al_2O_4 + Ca(OH)_2 = CaAl_2O_4 + 2NaOH$$

### Cost of Producing Silver

In his annual report for 1913, Mr. R. B. Watson, general manager, gives the following interesting data on Nipissing operations. The low-grade mill was in operation 86.8 per cent of the possible running time, and treated 77,240 tons of ore. Stamp duty was 6.09 tons per stamp per day. The recovery of silver from the beginning of operations on Nov. 11, 1912, to Dec. 31, 1913, was 91.85 per cent. The ore-treatment cost, based on the tonnage given above, was $4.132 per ton, distributed as follows:

| | Cost per Ton |
|---|---|
| Crushing at mine | $0.163 |
| Aerial tramway | .100 |
| Surface tramways | .117 |
| Picking plant | .217 |
| Crushing | .081 |
| Battery | .267 |
| Tube mills and classifiers | .547 |
| Slime collecting | .448 |
| Intermediate filtering | .127 |
| Treatment | 1.021 |
| Filtering and discharging | .186 |
| Clarifying and precipitation | .301 |
| Refining | .127 |
| Heating | .113 |
| Water supply | .031 |
| Construction | .286 |
| | $4.132 |

### Consumption of Supplies at Low-Grade Mill

| | Lbs. per Ton | Cost per Lb. | Total Cost per Ton Ore |
|---|---|---|---|
| Cyanide | 5.190 | $0.1500 | $0.7785 |
| Caustic soda | 3.200 | .0214 | .0684 |
| Lime | 6.640 | .0040 | .0266 |
| Aluminium dust | .568 | .3373 | .1917 |
| Aluminium plates | .268 | .2438 | .0654 |
| Aluminium ingots | .964 | .2207 | .2128 |
| Flint pebbles | 6.540 | .0098 | .0646 |
| Ore pebbles | 3.100 | .... | .... |
| Coal for heating | 30.160 | .0029 | .0881 |
| Power, K. W. H | 51.570 | .0115 | .5933 |
| | | | $2.0894 |

The cost of producing 4,552,173 oz. of silver in 1913, at both low- and high-grade mills, was 24.09 cents per oz., which is 6.7 cents higher than in 1912, when practically the same quantity of silver was produced, *viz.*, 4,688,000 oz. The increased cost is due to the fact that nearly half the production in 1913 came from low-grade rock, whereas in 1912 practically the entire production was from high-grade ore. The cost of producing silver in 1913 is distributed as follows:

### Cost of Producing Silver—Based on Production of 4,552,172.59 Ounces and 77,240 Tons Milled

| | Per Ton Ore | Per Oz. Silver |
|---|---|---|
| Hydraulicking and clearing land | $0.554 | $0.0094 |
| Diamond drilling | .093 | .0016 |
| Development and exploration | 3.685 | .0625 |
| Stoping | 2.191 | .0372 |
| Loading and sampling | .064 | .0011 |
| Assaying, engineering and research | .151 | .0025 |
| Administration and office | .381 | .0065 |
| Boarding house and camp maintenance | .278 | .0047 |
| Insurance and taxes | 1.013 | .0172 |
| General and legal expense | .366 | .0062 |
| High-grade mill | .618 | .0105 |
| Low-grade mill | 4.144 | .0703 |
| Custom Milling by Nova Scotia Co | .017 | .0003 |
| Depreciation | .793 | .0135 |
| Marketing product | .305 | .0052 |
| Corporation, New York Office and Travelling | .155 | .0026 |
| | $14.808 | $0.2513 |
| Less rents and interest | .615 | .0104 |
| **Total operating cost** | $14.193 | $0.2409 |

### Dominion Reduction Mill

This is a custom mill treating ore from the Kerr Lake, Crown Reserve, Cobalt Comet, Drummond Fraction and other mines in the district. The method of ore-treatment is outlined in Fig. 10. As the mill is run on a custom basis, few data of operation are available. One of the features of the dry crushing department is the recent installation of a 48-in. Symans horizontal reduction disc, the only one in the district.

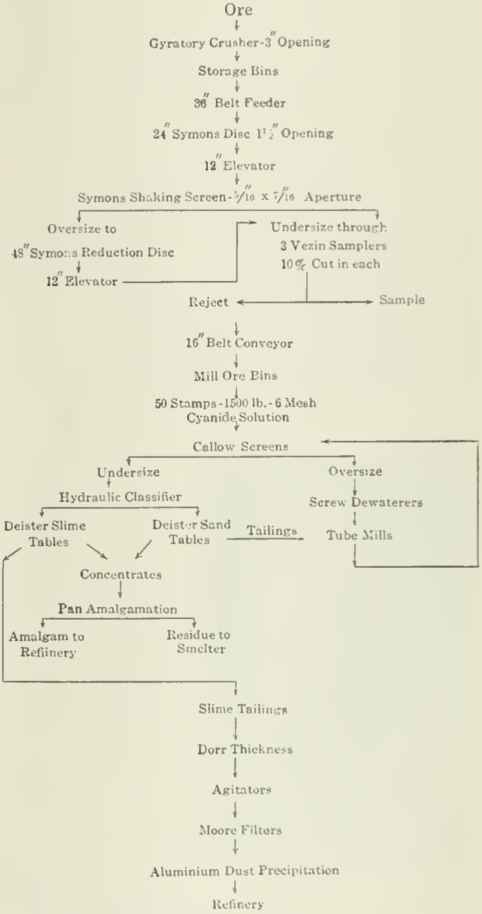

FIG. 10—FLOW SHEET, DOMINION REDUCTION MILL, COBALT

The ore is stamped in solution carrying 3½ lb. cyanide and 2½ lb. protective alkalinity. Sodium hydroxide and lime are used for the latter purpose, about one-third caustic soda and two-thirds lime. After sizing through Callow screens the pulp is classified for concentration, and sand tailings are ground in tube mills in closed circuit with the screens. Concentrates receive a special treatment by pan amalgamation in strong cyanide solution. The products are (1) amalgam, which is melted and refined, and (2) a residue containing about 150 oz. silver per ton, 33 per cent arsenic, 6 per cent cobalt and 3 per cent nickel. This residue is sold for further treatment.

There are no unusual features about the cyanidation of the slime tailing, except that aluminium dust is used as a precipitant of silver from the pregnant solution. The dust is fed at a constant rate of 3 lb. per hour when solution pumps are running, regardless of the grade of the solution. Mixing is accomplished in a small wooden tank, in the bottom of which runs a screw propeller that forms a vortex. Precipitation efficiency varies with the grade of solution and is more nearly complete when the solution carries about 10 oz. silver per ton. Thus from a 9-oz. head solution the tail solution carried only 0.12 oz., while from a 4-oz. head solution the tail solution would carry 0.82 oz.

In conclusion the writer desires to record his appreciation of the many courtesies extended during his visit to the mills in Cobalt, where every facility was afforded for gathering the notes on which these articles have been based.

## The Late Walther Feld

The death of Walther Feld on March 15, this year, in Linz on the Rhine, Germany, has left a void in the chemical profession which will be very difficult to fill.

Feld was a genial investigator, an unexcelled chemist and a never-tiring pioneer in the field of chemical technology, which, combined with a loving personality, made him a friend much sought after.

THE LATE WALTHER FELD

Feld was best known through his origination of the barium industries in Germany, and a walk along the banks of the Rhine shows plainly to what extent his labors in this field bore fruit, as the principal industry for many of these villages depends upon the production of barium compounds. He created this industry when there was no market for the product, but due to his untiring efforts, this market was found for the benefit of the present producers.

Being called upon to investigate tars and oils in coal gases, he was led to establish a theory of fractionately separating various tar products in the gas through distillation by the own heat of the gas, and his results in this endeavor can be pointed to with pride in many of the European coke-oven works. Having once taken in hand the condensation of coal gas, he did not stop until he had solved the old problem of purification in closed vessels—something which gas men had been seeking for the last fifty years. Not only did he make it possible to purify in closed vessels, but he was also able to combine the hydrogen sulphide contained in the gas with its radical of ammonia, and thus produce sulphate of ammonia* without the use of sulphuric acid, and perhaps his only regret before joining those in the Great Beyond was the fact that one of the largest installations of his direct sulphate recovery system, and which had been built under his supervision, was to be placed in operation ten days after his death. While this disappointment during the few days of his illness had to be borne, he still had the satisfaction of seeing the rosy dawn of success in a field which had been abandoned by many others.

While Walther Feld was not known as well in the United States as he was in Europe, his demise is of interest to all engaged in like pursuits, as he hoped that many of the chemical principles laid down by him would be followed by his brother chemists the world over.

In closing the notice of his death, nothing of greater praise can be said than the following words which appeared in *Die Chemische Industrie*, published in Germany, namely: "The barium industry as well as industries connected with tar and ammonia must thank him for the new paths which he has broken, and in the history of the development of German chemical industries the life work of Walther Feld must for all time remain an imperishable page of fame."

Fred. H. Wagner.

## Niagara Falls Meeting of American Electrochemical Society

For the fall meeting of the American Electrochemical Society, to be held in Niagara Falls from Thursday to Saturday, Oct. 1 to 3, the local committee has announced the following provisional program:

On Thursday morning there will be a session for the reading and discussion of papers, in the afternoon an excursion to Fosters' Flat, in the evening a smoker "with an unusual program."

On Friday morning a visit will be paid to plants and power houses, with a high-voltage display at one of the power houses. In the afternoon there will be a session for the reading and discussion of papers, and in the evening a dinner, followed by an illustrated lecture.

On Saturday morning and afternoon an experimental symposium will be held at the Fitz Gerald Laboratories, and in the evening a kommers at the Fort Schlosser Club.

The privilege of the local golf course will be extended to members. Other special features of the program will be announced later.

## Salt Lake Meeting of American Institute of Mining Engineers

The Salt Lake City meeting of the American Institute of Mining Engineers will be held from Monday to Friday, Aug. 10 to 14, 1914.

Technical sessions will be held in the evenings of Monday, Tuesday, Wednesday and the morning of Thursday in the ballroom of the Hotel Utah.

The program of excursions is very full and exceedingly interesting. Practically the whole of Tuesday will be devoted to a trip to the mines of Bingham, the concentrating mills of the Utah Copper Company at Magna and Arthur, and the Garfield smelter.

On Wednesday the smelter of the American Smelting & Refining Company at Murray and the smelter of the United States Smelting, Refining & Mining Company at Midvale will be visited in the morning and the smelter of the International Smelting & Refining Company at Tooele in the afternoon.

A trip to Saltair Beach is scheduled for Thursday afternoon and an automobile trip to Big Cottonwood Canyon, with picnic luncheon, for Friday. On the evening of Friday there will be a banquet at the Hotel Utah.

---

# Research Work in the Laboratory and Mill

BY WARREN F. BLEECKER

Technical men seem to be agreed that the time is not far distant when industrial concerns will realize very forcibly the necessity for greater efficiency in operations and processes of a chemical and metallurgical nature. Competitive conditions will probably require certain classes of manufacturers to produce not only better grades of materials, but also to produce them somewhat more cheaply than in the past.

We may also imagine a time, not far distant, when the people as a whole may caution owners of mines and mills not to waste by crude manufacturing methods substances which are at the same time useful and rare. New minerals will be found in workable quantities, and processes must be devised for them. Methods of treatment for lower-grade materials will be required from time to time. And finally it must come to pass that processes will be devised which will be dependent upon by-products from industries wholly diverse and unrelated.

These things are now being thought of more and more, and men of all grades of technical training and ingenuity are being called upon to attack the problems already discerned by farseeing directors of industrial organizations.

## Research Ability

It has been observed that a great many managers of plants, chemists, and young technical graduates have some difficulty in approaching certain classes of experimental work which they are called upon to do. This is especially true when a man does not possess a natural aptitude for research work, or in case the problem to be solved involves a branch not directly within his experience. For example, the manager of a wet concentration mill may find it necessary to investigate the possibilities of other methods of treating his ore, such as magnetic separation, or cyanidation. Facing such a problem, he should feel assured that he has access to certain avenues of investigation which are wholly within the limits of his ability and experience. The fact of his proficiency along his present line of work should give him assurance of being able to carry to a successful issue such experiments as he may undertake.

It is a distinct economic loss for a man of average intelligence to avoid lines of experimental work, essential to his business, but which he assumes to be out of his immediate mental grasp, because they happen to involve special knowledge somewhat apart from his previous experience. While it may take a lifetime to become an authority on electrometallurgy, for example, a working knowledge of the principles of this art may be acquired almost by wishing it.

While recognizing the necessity for expert and thorough knowledge we should not overlook the advantage of a perspective which embraces accurate detail and at the same time mellows it.

Each man who is doing his work well has acquired a certain mental equipment which is adapted to his present needs. I wish to point out that this equipment, with the aid perhaps of the knowledge of a few fundamental principles, will serve equally well in such new problems as may be attempted. In a word, nothing within reason is impossible to the man with sufficient courage to tear apart the veil of mystery surrounding unfamiliar fields and confidently examine the various elements. Such a procedure will yield ample returns for the small effort invested.

It would be unnecessary to offer suggestions to trained investigators and presumptious to advise men expert in their particular lines. But of these I ask the privilege of stating facts broadly, because once the attempt is made to state exceptions and to define the innumerable phenomena secondary to a given principle, there is immediately set up a perplexity, however small, in the mind of the beginner, and the entire purpose is defeated.

I do not think it necessary in the discussion of electrolysis, for example, to send out a general alarm as to the theories of osmosis, ionic migration, polarization, decomposition voltage, equilibria, and kindred phenomena. The specialist understands the importance of these things from sources of unquestioned authenticity; when the other fellow gets to a point where he can quibble over definitions and theories, he will not have been far misled by getting a few facts in the rough.

To him who has had the privilege of receiving instruction from high-class industrial engineers of our colleges and schools, or to him who possesses a genius for experimental work, I have but little to offer. It is to that class of men who are called upon to perform tasks somewhat outside their training or experience that encouragement should be given, not by laying down rules and laws for an indefinite number of specific cases which might arise, nor again to destroy or distort individual methods or habits of thought, nor again by attempting to diagram every imaginable case which might arise, but by speaking of certain basic principles, indicating possible avenues of approach, by assuring them that many new things are actually within their experience, and finally by pointing out a few sources of error and fallacy which are certain to be encountered.

## Scope of Metallurgical Research

Research may be undertaken with any one of a number of different objects in view. It may be desired to give an ore a preliminary treatment in order to obtain a product previously rejected; a demand may have arisen for the improvement of a certain product without an expensive and unnecessary improvement of other products; it may be desired to improve the grade of all products; some reagent used in the processes may have become more expensive or rare; a new and different ore body may demand treatment; a general shaking up of processes to the end of greater efficiency may be required; and there are hundreds of other reasons why researches are undertaken. In each case there will be found a logical chain of possible incidents between the requirement and the hoped-for result, and this chain ought to be diagrammatically stated for constant reference.

## Statement of the Problem

One of the first things an experimenter should do is to state his problem as definitely as possible in writing. He should state the result hoped for, the allowable variations of present practices, allowable costs, grades of products, available raw materials, etc.

I have found it useful to imagine a process or operation completed, and then look back over it to see what further could be desired. There is an old saying as to the superiority of hindsight over foresight. Sometimes one may be credited with considerable foresight when it has been nothing more than hindsight. I have heard this expressed a little more elegantly by one of my professors in mathematics. He called it "Back Illumination." This back illumination leads us to be more truthful with ourselves, for the reason that a careful survey of that which we are supposed to have done will surely reveal defects in a system which were at first sight hidden by our natural optimism.

I do not recommend that one should attempt to imagine all of the finished details at the outset. On the contrary, to determine details is the object of the research. But I insist that a plan of action should not be left to chance reactions and phenomena which may from time to time be observed. Before a series of experiments can be successfully attempted one or more properties or peculiarities must be known, which properties have the possibility of lending themselves either to or toward the end desired. When, as is often the case, advantageous properties are not known, a definite and thorough research must be made until they are found. It is not within the limits of my experience that this is impossible.

### Optimism Versus Proof

Without going into the psychology of the thing, I am convinced that there is no other profession which exacts from its members such a rigid adherence to truthfulness and honesty between man and man. In no other profession that I know of does there exist such an amazing and constant series of opportunities for optimism and hopefulness to shade into realities without the formality of rigorous proof. It is altogether too easy to assure one's self that a little more heat, a little more reagent, or a little more time will result in a higher extraction or a greater degree of purity, without actually performing the operation. Among other sources of opportunity for self-deception may be mentioned the neglect of traces of impurities which will surely multiply in finished products; lack of appreciation of the time element; neglect of allowance for wear and tear of apparatus, and finally, the failure to put down in cold figures the losses at various stages of the treatment through which a product must pass.

In all cases the experienced metallurgist will base his final conclusions on recorded observations. It is a practice to be recommended to the investigator who is working along lines in which he is not expert.

### The Importance of Qualitative Results

In the exploration of new fields, the importance of obtaining results which are only qualitative, can hardly be overestimated. The idea of the primary mass has even a more profound meaning in chemistry and metallurgy than in freehand drawing. If one will but take time to block out his problem he will obtain a perspective worth many times the effort. The technical research man must allow his train of thought and his habits a certain flexibility, in that he should be able to rush through almost countless operations, making them serve his purpose without the useless labor of completing each for the sake of art. In other words, he should be able to learn many lessons from unfinished work without jeopardizing his instinct of accuracy. I have found it a most difficult thing to train young technical men in the habit of knowing when an experiment is finished.

I will illustrate this point as follows: It is known that the values in certain radium-bearing ores may be partially separated by a system of concentration involving flotation in a fluid. Assuming that an experimenter in attacking this problem had determined with a gold pan, a microscope, and an electroscope, that the process had a commercial possibility, he might proceed to verify this in a number of ways, but I will suggest a simple experiment.

One hundred grams of ore pulverized to suitable fineness is agitated with water in a litre florence flask. After allowing this to settle for a few minutes, the supernatant slime is decanted off, more water is added, and the operation repeated. Washing is continued without regard to the quantity of water until further agitation removes no slime. Assuming that water concentration is to be alone considered, it is obvious that under the conditions the maximum values were removed from the coarser sands. In other words, providing all of the slimes were to be saved and all of the tailings were to be rejected, the difference between the analysis of the original ore and the analysis of the tailings, expressed in percentage, would represent the highest possible efficiency.

In order to ascertain the maximum limit of recovery, therefore, it would only be necessary to know the original value of the ore, the weight and value of the tailings. In this particular instance the labor saved in rejecting the slimes would be several times that necessary to wash and dry the tailings, because of the difficulty in filtering and drying the slimes. It will be obvious that this operation will have to be repeated a large number of times on the various classes of ore under consideration, and for this reason, the saving of time will be a great factor in getting without delay a solid foundation for the refinements which must come later on.

The same rule will apply during the study of the quantities of water necessary for concentration; once it is established that a certain separation can be effected, it is entirely unnecessary to check the results simply because there is an opportunity. Time is so very valuable that it should not be wasted in doing unnecessary work.

Almost all results which are obtainable in a small way, especially through the application of laboratory methods, cannot be taken at face value. In other words, they must have the proper interpretation before reliable conclusions can be drawn. The experimenter must by experience familiarize himself with large-scale operations before he attempts to draw conclusions as to costs, extractions, recoveries, grades of products, and other operating data.

### Laboratory Reactions

On the other hand, there are but few reactions peculiar to the laboratory. As a rule, mill operations are more nearly quantitative and may be obtained in a more satisfactory manner. Further than this there are certain classes of reactions which in the mill are almost marvels of simplicity and perfection but which are practically impossible in a small way. Among these may be mentioned magnetic roasting, salt roasting, gas washing, extraction by agitation, magnetic separation, wet concentration, and superheating.

Unfortunately there seems to be a widespread misunderstanding concerning the relation between laboratory work and mill operations. It is a very common belief that laboratory operations are very unreliable and even dangerous when considered as a basis of a proposed mill operation. That mistakes have been made and that a prejudice has been nourished therefrom, is due more to a lack of common sense than to inherent defects in small operations.

Chemical analyses do not, as a rule, give finished products, nor allow of simple multiplication in order to become of commercial application. While a standard method of tungsten assay results in the actual production of a minute quantity of tungstic acid, and the assay of gold results in the production of the pure metal, there are many other elements which are not determined by weighing small quantities of a finished, marketable product. Experience has taught us, however, that so many cubic centimeters of permanganate means a definite percentage of lime, and that a given quantity of standard cyanide tells us the percentage of copper. Because no further significance is attached to such reactions they have not fallen into bad repute by being introduced as mill processes.

One of the first things learned in chemistry is the group separation of certain of the elements. During that awful first year of the study of qualitative analysis the student picks up more misinformation than he can forget during the remainder of his life. While he is being taught methods he thinks he is learning principles. It is the application of these false principles which contributes so largely to the misunderstanding of the proper relation between experimental laboratory work and mill operation.

If one will only look upon laboratory experiments as sources of information and not as achievements; as indicative of detached facts rather than complete processes; as representing arguments, and not conclusions; we may then free ourselves from fundamental error in this matter. If we but realize that chemical reactions, like human actions, taken singly or in different settings, reveal tendencies rather than habits, the situation will be more sane, and our conclusions more worthy of our efforts.

It is often said: "Of course, you can do it in the laboratory, but in the mill it will be different." Nothing can be farther from the truth. In the entire realm of chemistry and metallurgy, I defy any man to mention as many as half a dozen operations which can be done only in the laboratory. A blast furnace is more efficient than a blowpipe, a jet of steam will heat a tank of liquor in the same time a beaker is heating over a burner, and with modern apparatus, tons of iron hydrate can be filtered, washed and dried as quickly as grams of the same material are likewise treated in the laboratory.

It is almost discouraging to find so many still speaking of the laboratory as a place where wonders are worked. I believe that it is possible to get at the bottom of such unscientific ideas and root them out forever.

It is, of course, a matter of common knowledge that the general conditions affecting chemical reactions are temperature, concentration, excess of reagents, presence of interfering elements, physical conditions of the reacting substances, and the tendencies of the various reactions to proceed at given rates. Among such a large number of conditions it follows that the number of combinations is very large. The lack of control of any one condition may mean lack of control of all; and there may be more than one condition during the inception of a process which is neither properly controlled nor understood.

In the treatment of small quantities of ore in the laboratory, there is always the danger of using a quantity of reagent entirely out of proportion to that which is allowable in a large way. Five cubic centimeters of sulphuric acid used to decompose a gram of ore containing 5 per cent copper means 182 tons of acid per ton of copper. Five grams of sodium carbonate necessary to decompose one gram of roscoelite carrying 2 per cent vanadium pentoxide means 445 tons of soda ash per ton of metallic vanadium.

The proper place to start an investigation is the laboratory, however large the final scale of operation is to be. There are a great number of reasons for this procedure, and, so far as I know, there are no reasons against it.

### The Process

It may be pointed out that the really important reactions of a new process are very few—usually not more than one. These reactions must be studied at close range in order to ascertain all favorable and unfavorable conditions. There will be numberless secondary reactions and phenomena, many of which will in themselves present problems. At best the thorough investigation of unfamiliar reactions and the resulting products requires scores, and sometimes hundreds of experiments. All else aside, with only one lifetime at his disposal, one cannot afford to begin a comprehensive research on a large scale.

We may arbitrarily divide an ore treatment process into three parts: the dressing of the ore, the extraction of the values, and the recovery of the products.

It will be apparent that no one of these departments may be completely organized without due regard to at least one of the others. For example, certain phases of roasting, concentrating, or leaching may determine the limits, and in a large measure the manner, of grinding. It is equally true that the separation or extraction process will have to conform to the requirements of the final production. In other words, the entire process will, as a usual thing, have to be built up as a unit. If the manner of grinding is decided upon before the extraction process is fully worked out, the experimenter has seriously endangered his prospects, because of the limits within which he must now work.

It often happens that the first-discovered and most desirable reactions of a series of proposed processes for ore treatment occur at a more or less advanced stage. In such cases the metallurgist will build toward such reactions from the ore pile, and from the finished products as well. The salt roasting of vanadium ores, and the dry chlorination of sulphide ores illustrates this principle.

### Magnitude of Experiments

It would be a serious mistake to confine experimental work to the laboratory until a series of processes are completely organized. Let it be supposed that a satisfactory extraction of a sulphide ore with chlorine could not be obtained in laboratory apparatus on account of lack of control of temperature, agitation, etc. It would, therefore, be necessary to use such apparatus as would give satisfactory results, although the ore for the experiments might have to be ground on a bucking board, and the resulting solutions treated in beakers. That is to say, because it is necessary to perform one of a series of operations on a large scale, I do not think it advisable to work on this scale entirely.

Archimedes, or Franklin, or Hubbard should have formulated a rule something like this: Get your information with as little expenditure of time, money, and material as possible, but get it.

A gentleman with the ink on his Doctor's degree hardly dry, approached a manufacturer with a claim that he could save a certain more or less valuable by-product at that time being wasted. That is to say, he had a process, admittedly in the embryonic stage, which sounded plausible to the manufacturer. After some discussion the chemist was employed and given permission to direct the perfection and installation of his process. Inasmuch as he had made no claim that the process had been tried or that it had been developed to the operative stage, it would have been the logical thing for him to have spent a few months or weeks as the case may have warranted in studying the proposed reactions and planning certain details. Instead of doing this, he ordered a quantity of special apparatus and began mill operation. Things went wrong here and there, and he started again and again until he had everybody disgusted and wishing him out of the way. Of course, he failed and lost what would have been a good job. As his proposition was afterward explained to me I am inclined to believe that it had merit, and that it was worthy of investigation. This young man could easily have made a showing if he had but realized the necessity for common sense. It does not require the intellect of a Newton nor the genius of an Edison to get results. One must have a good store of common sense and the courage to work, work, and work. If the idea is a good one, the results will finally unfold in an amazingly simple manner.

### Control of Quantities and Conditions

It is so easy to get rid of a small quantity of an objectionable impurity in the laboratory with a few drops of this or that reagent that the investigator may for the time pass over the possible cost or difficulties involved in a large way. It is also relatively easy to obtain a complete precipitation, or decomposition, or dehydration by adding a few drops of alkali, a few hundred milligrams of peroxide, or by adding a few calories of heat. Although it is not the usual thing, these factors may multiply geometrically when applied in the large way. This is not an uncommon thing in drying semi-colloidal precipitates; a cake twice as thick requires more than twice as long and much more heat for dehydration.

Another matter worthy of attention is that, as is well known, many reactions depend largely upon the strength of liquors, both as to valuable content and excess of reagents. For our purpose let us assume that the concentration of a solution as obtained from an extraction process is of the proper degree for precipitation. It is desirable to precipitate at or near the boiling temperature and this condition may be easily and quickly done by heating the solution over a flame. It will be obvious that while the concentration is not appreciably altered during the laboratory treatment, the method of heating in the mill will be different. More or less time may elapse between the extraction and precipitation in the mill as compared with the same operations in the laboratory, resulting in a loss of heat, and therefore requiring more time for heating. Although the solutions may be easily and cheaply heated by the introduction of live steam, dilution may occur to such an extent as to materially lessen the efficiency of the reactions.

Such obstacles are by no means fatal to processes, but they should be foreseen and plans for compensating for differences in concentration, etc., must be carefully worked out before one has the right to claim a successful issue.

### Interpretation of Results

It is almost a truism to say that the interpretation of quantitative laboratory results is quite as important as the interpretation of other phenomena which may fall under observation. For example, the fact that a certain extraction was obtained in the concentrating experiment mentioned above does not mean that exactly such results will be obtained in practise. It means that under the conditions of washing, etc., the limit has been reached, and that somewhat lower recovery may be expected. A microscopical examination of the tailings may suggest a slightly modified treatment, providing the possible recovery is not satisfactory. On the other hand, a careful examination of the slimes may reveal physical properties which will lead to the investigation of other modifications. The experiment has confirmed the supposition that a mechanical separation is possible and it remains for countless other experiments to completely disentangle the knot which Nature has so cunningly woven.

In the study of ore extraction, it often occurs in a series of experiments that after a given treatment the percentage extracted is strikingly constant. This is very significant in many cases, and may mean that the values exist in more than one state of oxidation, or that the treatment leaves unaffected only that quantity which is differently mineralized.

As a rule, one may obtain results in a large way which are more nearly quantitative than those obtained in the laboratory. Conditions of temperature, concentration, agitation, acidity, volume, etc., may be kept more nearly constant, and readily within the required limit.

In working with a new ore it is a part of the metallurgist's business to assure himself that the sample at hand is reasonably fair and representative; otherwise he may work serious injury to himself and his employer. The whole, if practicable, should be thoroughly mixed and sampled according to standard methods, and in almost all cases, a complete analysis should be made.

### Some Valuable Accessories

Assuming that ore treatment is under discussion, it is a very natural thing to make a preliminary survey with the aid of a few simple accessories before undertaking a profound research. For example, the following equipment is indispensable:

A complete set of screens.
A rough balance, 1 gram to 1 kg.
A gold-washing pan.
A horseshoe magnet.
A powerful reading glass.
A microscope with micrometer slide.

With the screens, the experimenter will be able to determine among other things whether the vaules are evenly distributed throughout the gangue, or segregated to a greater or less degree in portions having different hardness, or other physical property affecting the size. A screen test may also indicate the proper fineness of crushing and at the same time indicate possible losses through dust and slimes.

A gold-washing pan may reveal the presence of elements which were not suspected, and will sometimes bring to light minerals which are present in quantities so small as to escape detection in the process of chemical examination.

A most valuable aid to the metallurgist is the microscope. With it one may not only study the size, form, structure and other characteristics of ore particles, but also observe certain classes of chemical reactions. With a few milligrams of ore on a glass slide one may study the action of such solvents as may be thought worthy of trial, and the resulting solutions may be further examined under moderately high power in investigating certain phases of precipitation or purification. As the dynamic test of metals discloses properties ont even suggested by static tests, so the microscope will reveal facts beyond the ken of the analyst. For example, a very excellent and certain method of controlling the roasting of telluride ores was devised by Mr. Willliam H. Davis in Boulder County. He suspected that the diminishing sulphur content of the ore as roasting proceeded was not a true index of the decomposition of the telluride mineral. Accordingly he took samples at various stages of the roasting process and separated the gold-bearing mineral from the gangue by washing in a gold pan. An examination of the minute particles from the various samples under the microscope at once showed the physical and chemical conditions resulting from under-roasting, properly roasting, and over-roasting. Mr. Davis not only proved his point, but succeeded in obtaining an extraction much higher than when using only chemical control.

### A Study of the Ore

In the study of ore extraction it is always desirable to know, if possible, the manner in which the values are combined, both chemically and physically. With such information it is usually not difficult to attack the mineral directly, and in some cases it is quite possible to leave the present gangue matter wholly unattacked.

In some classes of ores it is also necessary to know the potential reduction. This together with a knowledge of the analysis, will usually throw much light upon the existing conditions of the values, as to whether they are partially reduced or partially oxidized. An ore may be examined as to its state of oxidation in several ways, such as weighing a portion which has been previously ignited under such conditions as will remove the combined water, organic matter, etc., and subsequently oxidizing and noting the increase in weight. In an experiment with ore containing sulphur or certain other elements, it will obviously require various and ingenious methods to avoid compensating errors, but there is usually a way to do it. A partial solution is some neutral reagent, such as sulphuric acid, and direct titration with standard permanganate or some other agent will also lead to information.

### Value of Approximations

The research engineer should accustom himself to grasp the meaning of percentages rapidly, and should be able to make such rough mental calculations as will at times allow quick work. Refined calculations are of great importance and have their place, but rough and ready approximations will save valuable time and material. A set of lead chambers could be seriously damaged if the man in charge stops to figure when he sees a storm coming up, or if he finds that the nitre man has forgotten his charge an hour ago.

Together with this faculty of rapid approximation should go a keen sense of order of magnitude. This is a most useful possession and will keep one from many errors, plausible enough on the face, but easily recognized by their very absurdities. For example, men who have a properly trained sense of the order of magnitude are almost free from errors resulting from a misplaced decimal point, especially in slide-rule calculations. The technologist should have such an intuitive sense of the fitness of things that will cause him to question at once results, sizes and forms which are not in keeping with accuracy or good practise.

Often in working with new products which are not of enough importance to warrant the development of routine analysis, the analyst may report results which seem to him to be perfectly reasonable, but which to the metallurgist are absurd. Perhaps I may have been unfortunate in meeting men whose ideas of the fitness of things were limited, but my experiences have convinced me that the problem is real.

### The Order of Magnitude

A gentleman with several letters after his name suggested to me in all seriousness the catching of rainwater in an open tank for the purpose of supplying a plant with distilled water. That a year's rainfall would not have lasted an hour did not appeal to him in the least. The story of the engineering student who designed a brace one one-hundredth of an inch in diameter is surely not exaggerated. I knew an engineer who attempted to stop a hole threaded for ½-in. pipe by simply shoving in a short ½-in. bolt. He explained that he couldn't find a ½-in. plug and that the bolt would keep in some of the water anyway.

A certain large engineering concern was permitted to do the engineering on an electrode-regulating device. They were told that the electrode and holder would not weigh more than 100 lb. They sent a mechanism guaranteed to lift something like 9000 lb. Another engineering firm in or about New York City sent out a generator with a rated amperage of 2650, while the copper busbars from the brush holders had a section of less than half a square inch. In addition to this, the connections between the brush holders and these bars were of cast iron.

We see advertisements of washing machines which will do the family washing for 2 cents, and of an apparatus which will furnish distilled water at less than 3 cents per ton. I think the whole matter is worthy of serious consideration.

The experimenter should be constantly on the lookout for unusual reactions and phenomena, and be prepared to take advantage of them, should they be suited to his purpose. It is usually upon reactions somewhat out of the ordinary that new processes are based. In other words, the most successful technologist does not always think of copper in terms of a hydrogen sulphide precipitate.

In the investigation of a complete process of ore treatment the experimenter is trying to determine two things: the efficiency of the process, and the cost. To a large extent these two things are interdependent, although the first question is answered only by experiment, and the second may be answered largely by calculation in many cases.

It must be remembered that the cost per unit of value recovered is finally going to be the point upon which the success or failure of the process is determined. A low efficiency at low cost is usually more likely to prove profitable than a high efficiency at high cost. The experimenter must at all times keep in mind certain limits beyond which he cannot go in the use of expensive chemicals, quantities of chemicals used, and the number of operations through which the ore and products must pass.

### Choice of Reagents

Excepting for the purpose of obtaining information of a strictly chemical significance, it is usually not advisable to make use of reagents which are known to be inapplicable to mill use. This, of course, depends wholly upon the nature of the problem, and the manner of attacking it. There is a tendency with all of us to ward the use of such powerful reagents as nitric acid, sodium peroxide, potassium chlorate, metallic zinc, concentrated sulphuric acid, and the like. These things do have limited uses in large operations, but one should have a thorough appreciation of quantities, costs, and difficulties of handling such chemicals before attempting to use them in works operation. A good example of the use of an expensive reagent in the treatment of very low-grade ores is found in the cyanide process. This process, however, is a law unto itself and its like is hard to find. The use of mercury for amalgamation, and the use of platinum in the contact process are other examples, illustrating the absurdity of formulating a rule to be followed blindly. It may be said, however, that the use of expensive reagents must be accompanied with more care and expert attention than the use of such materials as common salt or sulphuric acid.

There are many instances in laboratory experimentation in which an expensive reagent may be used as a matter of convenience and saving of time. For example, it is sometimes desirable to oxidize solutions in order to obtain favorable conditions for precipitation or filtration. In the laboratory the easiest procedure is to add hydrogen peroxide. Quantitative experiments and subsequent calculation will usually show that for a given oxygen content sodium peroxide is cheaper, liquid chlorine is cheaper still, and finally electrolysis is the cheapest of all. Under some conditions air may be used for oxidation of solutions, and besides its cheapness it has other very desirable properties. The experimenter is entirely justified in using peroxide of hydrogen for his small experiments, providing he is certain it has no other effect than the addition of oxygen and that the method finally to be employed is likewise applicable.

### Cyclic Processes

In general, the experimenter should be cautious in the contemplation of cyclic processes; that is, those which involve the recovery of reagents over and over again. The chief source of danger in processes of this nature is the accumulation of impurities which finally render the solution inactive. An example of a successful cyclic process is the chamber process for making sulphuric acid. Although the conditions are highly favorable for the recovery of nitric acid and its subsequent reuse, it is significant that the nitre pots are very important adjuncts to the plant.

There was proposed not long ago a process for the treatment of ores with nitric acid. The nitric acid solutions containing nitrates were to be treated with sulphuric acid, and the nitric acid recovered in absorption chambers such as are used in the processes for the fixation of nitrogen. The difficulties to be encountered at the various steps of the process would probably be very great, but this is not all. The designer of the process evidently overlooked the fact that nitric acid owes its activity to the ease with which the $NO_3$ ions decompose. Thus the thing is defeated even before it has begun.

Perhaps the most satisfactory cyclic process of large magnitude is the cyanide process. The history of the development of this process shows that the early investigators met with their share of trouble, and but for the fact that it was so revolutionary and so necessary, it is altogether possible that it might long ago have been relegated to the metallurgical graveyard.

The continued reuse of solutions in processes for the extraction of copper has been tried repeatedly, and in some instances with a measure of success.

Under certain favorable conditions it is possible to recover chemicals with profit. As a rule, however, it is more desirable to adopt counter-current systems of leaching and washing in order to get the full value of the reagents added, and finally discard spent and barren solutions together with whatever impurities they may carry. Spent solutions of acid and alkali are not often recovered with profit.

### Electrometallurgy

It is generally conceded that the application of electrical energy to metallurgical operations is increasing geometrically. Representing as it does a form of energy powerful yet easily controlled, ready for work at the throw of a switch, it is all the more remarkable that still greater use is not made of it. Rapid as the advance of electrometallurgy has been, it deserves to come into greater use. To my mind, the greatest retarding influence is the lack of full appreciation of the possibilities of the application of electrical energy to ores and ore products.

To the research man, unfamiliar with the commercial application of electrical energy, it may be said that the experimental difficulties in this branch of work are no greater than in any other. As in any other branch of science, there are certain rules and laws to be understood, but they are of interest and wholly logical. After all, common sense is nine-tenths of the electrometallurgical game.

Aside from power and lighting purposes, electricity is employed in metallurgy for two general purposes: heating and electrolysis.

Electric current may be supplied either as alternating or direct, the greatest difference between these two forms being that in the one case the current is rapidly reversed throughout the circuit, and in the other the flow is constantly in the same direction. The very rapid reversing of a current gives rise to effects not met with in direct current, but which for our present purpose need not be discussed.

While either alternating or direct current may be used for heating purposes, only direct current can be used for electrolysis since in this latter phenomenon a continuous removal of electric charges is brought about at opposite electrodes. It may be considered that negative charges are given up at the anode and positive charges given up at the cathode. Obviously, electrodes connected to a source of alternating current become consecutively positive and negative in such rapid order that the electrolytic effect of one instant is destroyed or counteracted during the next.

In the electrolytic cell or electric furnace it is desired to obtain all of the energy potentially in some form of matter: a pound of aluminium, a pound of silicon, a pound of zinc, each represents a definite number of kilowatt-hours of electrical energy.

### Electrolysis

An impression which is more prevalent than is generally supposed, is that the electric current by virtue of its passage through a solution or other medium, exerts force upon it in such a manner as to cause chemical reactions to take place regardless of any strictly chemical habit to the contrary. In other words, it is wrongfully assumed that the electric current may set aside chemical laws and perform various chemical acts wholly impossible without its aid.

We may assume that the electric current creates no chemical change in the interior of an electrolyte and be entirely correct. Any effect of the electric current which concerns the technical investigator is due to the removal of electric charges from chemical elements or groups of elements (ions) at the electrodes, and at no other place. What the current really does is to change the electrical conditions of compounds which are in contact with the electrodes and thus allow the element so electrically discharged a certain chemical freedom. The exercise of this freedom is sometimes mistaken as a phenomenon of the current itself.

If we will allow ourselves to look at this thing from a common sense point of view, we may for a time place to one side the mass of theories and highly specialized information (which indeed we shall find of great value later in our experience) and observe the action of electrolysis as a thing of extreme simplicity. What the practical man wants is results. If he has a sound working knowledge of electrolytic phenomena, he may not yet know all that is possible, but he certainly will know that some things are impossible.

### Electrolytic Decomposition

The following illustration has been chosen as typical of electrolytic decomposition:

Sylvanite, a telluride of gold and silver, may be decomposed in an electrolytic cell. It is only necessary to place the crystals in contact with the cathode of a cell, the electrolyte in which is sodium hydrate. The tellurium is rapidly dissolved, while the gold and silver settle to the bottom as a black powder. The electric current releases metallic sodium on the surface of the crystal and from this point on the action is strictly chemical, and would take place if the current were discontinued. If the tellurium compound were placed at any portion of the solution not in contact with an electrode it would remain unchanged, however much electrical energy might be passing through the cell. If the electrolyte were sodium chloride and the sylvanite were placed on the anode decomposition would result from the action of the chlorine deposited upon it. In this case the gold would go into solution.

### A Maximum Chemical Concentration

The electrolytic cell provides a very efficient means of obtaining a maximum concentration of elements or groups in a state of freedom. For example, by the electrolysis of a salt of sodium we may obtain a decomposition at the cathode such as would be possible with sodium element, because, indeed, we actually plate metallic sodium on the cathode and any conductor of the first class which is in contact with it. Likewise we may get the action of pure chlorine by electrolysis of a chloride. The products of electrolysis are formed in relatively small quantities, and in many cases instantly reunite, but they continue to be formed as long as the electrolyte holds out and the current continues to pass.

### Secondary Reactions

When common salt is electrolyzed, the two products are sodium and chlorine. The chlorine is partly dissolved in the solution and partly evolved in the gaseous state. The metallic sodium is immediately set upon by the water present and sodium hydrate results. The chlorine which is dissolved reacts upon the sodium hydrate to form hypochlorite, and other reactions occur, depending upon conditions of temperature, concentration, etc. It is obvious, however, that the formation of caustic or hypochlorite results from purely chemical causes, and would take place if metallic sodium were placed in water, or chlorine were led into a solution of lye.

### Electrode Phenomena

If the electrolyte be sodium sulphate there will be plated at the respective electrodes, sodium and the group $SO_4$. Since neither of these can exist alone in aqueous solution, a decomposition of water takes place with the evolution of hydrogen at the cathode and oxygen at the anode. It will be perfectly apparent that if the anode is of such a material as will form a soluble sulphate, it will be attacked and dissolved. It will also be apparent that by proper selection of electrolyte and electrodes the full effect of either the hydrogen or the oxygen may be obtained for reduction or oxidation respectively. For chemical and mechanical reasons, the size and shape of the electrodes have to be considered, and to obtain the best results, the electrodes must be proportioned according to the current available and the effect desired. Either oxidation or reduction may be obtained by properly regulating the relative size of the electrodes.

In the greater number of electrolytic operations it is desirable to use an anode which is not attacked. Unfortunately our choice is limited to platinum, graphite, fused iron oxide, lead or gold in some cases, and possibly a few others. In case the cathode is metallic, it will not be attacked. In case the cathode is an oxide it will either be reduced in situ or dissolved and finally find its way to the anode. As an illustration showing how both of these effects may take place simultaneously, a plate of copper vanadate (a compound of copper and vanadium oxides) employed as a cathode will become a plate of sponge copper, while the vanadium pentoxide will be dissolved and tend to be plated out on the anode.

There are many desirable reactions which may be obtained by using a soluble anode; that is, one which is attacked by the negative group or element plated out upon it. For example, vanadate of lead may be formed by electrolyzing a solution of sodium vanadate and using a metallic lead anode. Likewise tungstate of iron may be made by using an electrolyte of sodium tungstate with an iron anode.

The electric current will of itself neither oxidize nor reduce, neither decompose (except the electrolyte itself) nor synthesize; but it will give freedom to elements and groups of elements which in turn will do these things. Such is electrolysis.

Compounds may be broken up by virtue of their elements having been plated out at the electrodes, and these elements may reunite to form either the same or different compounds. The formation of such salts would take place at the moment, however, if the current should be discontinued.

Electrolytic cells may be divided into two general classes: those in which the two electrodes are in the same compartment, and those in which the electrodes are in separate compartments.

In the simple cell there may be obtained such reactions as electroplating, refining of metals, production of metallic salts by anodic decomposition, oxidation, reduction, etc. In the compartment cell, of which there are several types, there may be obtained practically all electrode products, the cathode material being kept separate from the anode material. Perhaps the largest industrial application of the compartment cell is in the manufacture of caustic soda and chlorine.

### Compartment Cells

The most widely used type of compartment cell is the diaphragm cell, in which the electrodes are separated by a porous partition. This partition serves to prevent mechanical mixing, but allows the passage of positive and negative elements and groups which finally reach the electrodes and become electrically discharged and free. Depending upon its porosity, the diaphragm will also allow a certain amount of diffusion and the resulting contamination of the compartment product. The investigator may make a diaphragm of filter paper, canvas, wood, clay, asbestos, alundum, silica, or in fact of any porous non-conductor. For very small experiments, porous cups may be used. At one time I used large flower pots with considerable success.

Another type of compartment cell is one in which the electrodes are separated by glass or other insulating material, the partition extending into a bath of mercury. The mercury may be connected directly as a cathode, or in certain rare instances it may serve as a pair of electrodes. In this case the electrodes which are connected to the source of energy are suspended above the mercury, one on each side of the partition, the mercury in the positive side becoming negative, and in the negative compartment becoming positive.

A third type of compartment cell is one in which the electrodes are separated by a partition which extends below them, but which does not touch the bottom of the cell. Gaseous products, such as oxygen and hydrogen may in this manner be kept separate, or one gaseous product may be removed and a product from the other electrode allowed to remain, either in solution, or as a precipitate.

It will be obvious that the principle of electrolysis mentioned above holds for all classes of cells. Different designs are only for purposes of convenience, economy, and for taking advantage of the fact that at a given moment two components of a compound are chemically free and separated from each other mechanically.

After one has become familiar with the general principles of electrolysis and has personally observed the phenomena of such cells as he may construct, the various texts on the subject will be read with great interest and profit. To the investigator who is not of a mathematical turn, it is suggested that he get what he can out of these books which come under his observation in which mathematical expressions are frequent. It is a very rare thing indeed that an author succeeds in concealing all of his thoughts from the fellow who is after facts.

### The Electric Furnace

In the broadest sense, the electric furnace is an apparatus for the transformation of electrical energy into heat and applying this heat directly as desired. The heat is always obtained by the introduction of resistance to the passage of the current. This resistance is always in the furnace itself and may be obtained in a large number of ways, depending upon the effect desired.

No experimenter who may have occasion to attempt electric furnace investigation should be without a good descriptive text such as Stansfield or Blount.

The construction of an electric furnace is a very simple matter. The first experiments will usually be of a qualitative nature, and experience will indicate changes after each furnace operation which will require different shapes and sizes of crucible, different placing of electrodes, and different manner of lining. Build the furnace as easily and quickly as possible at first and do not worry over losing a little heat. There is a special economic law allowing quite large losses in experimental work.

### Qualitative Experiments

It is a waste of time in the beginning to calculate and weigh slag components and reducing agents too closely. Since the dust and gas losses, amount of lining chewed up by the slag, the action of the bath on the electrodes, etc., are not known, more can be learned by a few trial heats than by much calculation.

It is also a waste of time to worry over the chemical constitution of compounds which are to be smelted. It is a safe rule to follow that the electric furnace will reduce the various oxides to a common denominator in a short time. The thing to know is the oxygen content, the base metal content, and about what sort of slag the impurities will form. It makes no difference whether the iron oxide is combined with the alumina, the silica, or both, so long as the ultimate analysis is known.

### Interpretation of Results

Accurate notes should be kept of all important matters, such as quantities, time, instrument readings, etc., but they usually have no direct meaning. There is almost nothing in the first stages of any kind of experimental work which does not have to be interpreted. The fact that one uses two pounds of electrode for each ounce of metal produced has but little bearing on the problem as a whole. In technical journals and society transactions we sometimes read very painstaking reports of experiments, giving electrical efficiencies, recoveries, electrode losses per pound (or per gram), and in fact drawing supposed conclusions of commercial practice from the data per se. The results of the small experiment are of value only if understood.

### Power Supply and Apparatus

Some who may wish to attack a problem by using electrical energy, may be held back by the fact of having no available supply of power suited to their requirements. To these I suggest a conference with the local manager of the power company, and failing to get him interested, a meeting with the head officials will get results. It is known that experiments with electric furnaces and electrolytic cells lead to the consumption of power, and I have never met with a power company which would not meet me more than half way in developing new demands for their product.

One may borrow old transformers, or rent a secondhand generator. I once bought an old transformer core for $4.90; an additional $20 paid for the copper windings and small incidentals, so that the complete transformer cost about $25. I could obtain as high as 30 kw for an hour or so and 20 kw continuously.

An electric furnace may with economy replace gas or coke furnaces in many instances. For example, a cyanide mill may be somewhat remote from the railroad, but may have electric power. Instead of hauling gasoline for refining, it would be a very simple matter to construct a small electric furnace holding a No. 60 crucible, and the cost of operation would be very small. In fact, the losses attendant upon working around the usual coke or gasoline furnace would more than offset any difference in cost. When using a coke-fired furnace the gold is refined by a man who has to protect himself from the heat with an asbestos face mask and a suitable shield for his body. One may work with an electric furnace at 1200 deg. C. with bare hands.

I believe an electric furnace will be devised which will enable zinc smelters to redistill blue powder and dross much more efficiently than in the retort. It has been recently said that the trouble with electric zinc smelting processes usually was that the inventor endeavored to cause the zinc vapor to go in one direction and the gases of combustion in another. The writer of the article was of the opinion that this was an obvious impossibility. I am not so sure about it; in fact I rather expect that furnaces will be devised which will do this very thing.

### The Economic Phase

While attacking a problem of ore treatment with purely mechanical means, hydrometallurgical methods, electrolysis, or smelting (electric or otherwise), the economic phase must not be lost sight of. Unfortunately, no rule can be formulated giving limits between which a profitable cost of treatment might lie. This is because there are very few, if any, standard methods of treatment which will deliver a metal or other product at a cost which bears a fixed relation to the selling price.

There are, however, certain factors which may be calculated with some accuracy in each specific case, which when given their approximate cost value, will permit of a reasonable deduction being made from the gross value of the ore. These factors, among which are cost of mining, crushing, interest, depreciation, maintenance of laboratory, and allowance for actual recovery (60 per cent, 70 per cent, 80 per cent, as the case may be), can be determined with reasonable accuracy by reference to published data on costs of standard operations.

It will then appear that an ore which has a gross value of $20 per ton will have a value of somewhat less after making a fair deduction representing costs up to the process proper as suggested above. There will also be a shrinkage of values on the other end, such as transportation, penalties, smelting charges, etc., all of which lie between the material as produced and its market value in a finished condition.

Between the limits imposed by the shrinkages as set forth there lies a domain of values which is affected by the process itself. Here may be found the profits if the process is not too expensive.

As a corollary it may be said that the more standard operations one can employ in devising a process, the more accurate will be his cost estimates.

In conclusion, I wish to call attention to the fact that I have tried to deal solely with generalities, using specific instances only as illustrations and not in any sense as descriptions. I have endeavored to state facts and opinions in such a manner as not to give offense to specialists, and although there is an obvious appeal to research men for discussion and other angles on experimental work, there is implied no challenge.

I owe much to Mr. Arnold J. Guerber, chief chemist of the Standard Chemical Company, who has made many criticisms and suggestions.

Canonsburg, Pa.

## Electrolysis of Fused Materials Containing Zinc

"The Electrolysis of Fused Material Containing Zinc" is the title of a paper by Mr. Chun Hao Wang presented as a thesis for the degree of Doctor of Philosophy at Columbia University. The investigation was carried out at the Columbia School of Mines under the direction of Professor Edward F. Kern.

The first part of the paper is a review of existing literature on the electrolysis of aqueous zinc salt solutions, the precipitation of zinc from fuse baths, and the electrothermal treatment of zinc ores. Mr. Wang points out that before the electrolysis of fused zinc electrolytes can be carried on to advantage, there must be found a salt or a mixture of salts which is fusible at a temperature below the boiling point of zinc (920° C.), which is a good solvent for zinc sulphide or zinc oxide, and which will not volatilize at the temperature at which the electrolysis must be conducted.

In order to obtain these data the following experiments were conducted by the author:

1. Determination of the freezing points of several salts and mixture of the same.
2. Determination of the solubility of zinc sulphide and of zinc oxide in the salts, and in the mixtures, whose freezing points were determined, and the freezing point of the resulting fused solution.
3. Electrolysis of the fused solutions of zinc sulphide and of zinc oxide, finally selecting that bath which gives the most promise for the recovery of zinc from zinc sulphide, or from zinc oxide, by electrolysis.

The results of the experimental works on freezing points and solubility may be summed up as follows:

Sodium hydroxide freezes at 312° C. The addition of sodium tri-sulphide (freezing point 650° C.) up to 35 per cent causes a rapid rise of the freezing point. Above 35 per cent of sodium tri-sulphide the mixture solidifies in two layers.

Sodium tri-sulphide and mixtures of sodium tri-sulphide and hydroxide, are good solvents for zinc sulphide and zinc oxide (2 to 7 per cent zinc).

Calcium chloride freezes at 744° C. The addition of sodium hydroxide causes a reduction of the freezing point, which is intermediate of the freezing points of the components of the mixture.

Zinc oxide and zinc sulphide are soluble in calcium chloride and in mixtures of calcium chloride and sodium hydroxide only to a small extent (below 0.7 per cent zinc).

Sodium thiosulphate freezes at 804° C., dissolving over 1 per cent zinc either as zinc sulphide or zinc oxide.

Sodium silicates: Sodium bisilicate freezes at 1002° C. The increase of base up to 57 per cent, corresponding to sodium sesquisilicate, causes a decrease in the freezing point to 950° C. The further increase of the base up to 67 per cent, corresponding to sodium monosilicate, raises the freezing point. Sodium monosilicate solidifies at 1025° C.

Undercooling occurs with sodium silicates which have a silicate degree varying between the bisilicate and monosilicate. Undercooling is prevented by stirring the cooling mass.

The formation temperature of sesqui-sodium-silicate from a mixture of three molecular equivalents of sodium carbonate, and one molecular equivalent of silica is about 1200° C., whereas the freezing point of this silicate was found to be 800° C.

Boric anhydride in certain proportions causes the reduction of the freezing points of sodium silicates. An excess, in the case of the silicates containing more than 40 per cent of silica, causes the mixture to become mushy. The addition of zinc oxide to sodium silicates containing about 25 per cent boric anhydride raises the freezing point of the mixture.

Calcium fluoride lowers the freezing point of sodium silicates, producing a thinner fusion. The addition of zinc oxide to these mixtures containing 10 to 22 per cent calcium fluoride hastens the solidification of the resulting mixture.

The author's experiments on the recovery of zinc by electrolysis of fused solutions may be summed up as follows:

The zinc which was liberated by electrolysis is of fused sodium silicate, and sodium tri-sulphide baths collected as pellets, which remained in suspension in the fused electrolyte.

A bath of sodium bisilicate containing 25 per cent of boric anhydride, 22 per cent of calcium fluoride and zinc oxide (2.3 per cent zinc) after electrolysis showed a loss in the weight of the zinc bottom which was added at the start.

A bath of sodium monosilicate containing 20 per cent of boric anhydride and saturated with zinc oxide (5.8 per cent of zinc) showed great corrosion at the anode. In one case 32 grams of deposited zinc were collected by the metallic bottom (current efficiency 14.7 per cent), while in the other runs there was neither loss nor gain in weight of the bottom. Zinc flame was liberated around the cathode surface. The zinc was found in the cold solid bath as disseminated pellets.

Reversing the current for a short period previous to the electrolysis was found to be beneficial in electrolyzing fused electrolytes containing zinc.

The electrical conductivity of the fused sodium silicate baths containing boric anhydride increases with the decrease of the silicate of the mixture.

Fused baths composed of sodium hydroxide and sodium tri-sulphide containing zinc sulphide have higher electric conductivity than the fused sodium silicate electrolytes containing zinc oxide.

Sodium tri-sulphide baths containing zinc sulphide (5.8 per cent zinc) gave a very thick layer at the bottom which, however, was rendered fluid by adding lumps of sulphur.

The zinc liberated from fused baths of either sodium silicate or sodium tri-sulphide, saturated with zinc, does not collect as a mass on the cathode, but as pellets, which are mechanically carried into the fused electrolyte and held in suspension. This was also found by Thomas and others to take place in their fused zinc baths, which they attributed to be due to the formation of colloidal zinc, or zinc mist at the cathode. This, however, may be due to the high surface tension of zinc at temperatures near its boiling point.

The low efficiency of electrolysis of fused baths containing zinc is due to the zinc forming as pellets on the cathode, which are carried back to the anode and there oxidized and redissolved. Another cause of low efficiency is the loss of zinc partly by volatilization, due to the high current density at the cathode, the temperature at the surface of the cathode being higher than that of the bath.

By surrounding the cathode by means of a refractory condenser, the electrolysis of fused zinc electrolytes may be conducted at temperatures above the boiling point of zinc, collecting the deposited zinc in the condenser.

## The Determination of Phosphorus in Phosphor-Bronze

BY E. W. HAGMAIER

Phosphor-bronze is one alloy of which the chemist cannot say much as to phosphorus content until he has obtained the precipitate of phosphorus. Alloys called phosphor-bronze may contain anywhere from zero to 1 per cent or more of phosphorus. An experienced analyst may get somewhat of an idea as to whether the phosphorus is high or not by observing the condition of the metastannic acid in dilute nitric solution. If the phosphorus is ½ per cent or so, the metastannic acid will keep the original form of the drillings, after the copper, lead, etc., have gone into solution. The metastannic acid will be a grayish black when on the filter paper.

The writer has had occasion to analyze numerous phosphorus alloys in the last year and a half, and while doing so worked out an accurate and rapid method which will follow after a brief review of some of the older methods.

One method which is used a great deal is as follows: Dissolve one gram of the alloy in 30 c.c. of (1-1) nitric acid, and evaporate to a paste. Take up with a little dilute nitric and hot water, and boil to dissolve the copper, lead, etc., which has separated out. Remove from the hot plate and filter. The phosphorus is with the metastannic acid, provided there is sufficient tin present. The writer's experience has been that 6 per cent to 8 per cent of tin will hold up over 1 per cent of phosphorus. This precipitate is ignited in a tarred porcelain crucible, and the weight of the combined oxides of tin and phosphorus recorded. Potassium cyanide is then added to the crucible, and a fusion made. This converts the tin to metallic tin, and the phosphorus to potassium phosphate. The melt is then leached out with water, and the tin filtered off. The filtrate is made acid with nitric acid and boiled to drive off the cyanide. After all is driven off filter off any silica which may have come from the fusion attacking the crucible. The phosphorus is then precipitated in the usual way, and is determined and calculated to phosphorus pentoxide. This weight is deducted from the weight of the combined oxides already found, and the tin calculated.

This method will require at least two and one-half hours to get the phosphorus precipitated. It is necessary to run a blank on the potassium cyanide unless a special phosphorus-free cyanide is used. The amount of tin must always be sufficient to hold up all the phosphorus; that is, 6 per cent to 8 per cent of tin for 1 per cent of phosphorus, otherwise it is necessary to add sufficient tin or some of the phosphorus will go in the filtrate with the copper, lead, etc.

Another method quite frequently used is to make a sodium carbonate and sulphur fusion of the combined oxides of tin and phosphorus, leach out with water, and filter off any sulphide of copper which may have been held with the tin. Make the filtrate slightly acid with hydrochloric acid, and filter off the sulphide of tin, boil off excess hydrogen sulphide, add nitric acid, evaporate to a low bulk, cool, add excess ammonia, then nitric acid, and precipitate the phosphorus.

This method is by no means shorter than the previous one, and it is next to impossible to wash the sulphide precipitates free from phosphorus.

A modification of the previous method is used by some chemists. An aquia regia solution of the alloy is made, excess ammonia added, and the solution saturated with hydrogen sulphide. The sulphides of copper and lead are filtered off, then the filtrate is made acid with hydrochloric acid, and the tin sulphide removed. The phosphorus is then determined in this filtrate.

This method is the least satisfactory of any. It is next to impossible to wash the phosphorus out of the sulphide precipitates.

One can readily see that the foregoing methods are long and rather objectionable. With the idea of saving time and at the same time increasing the accuracy the writer conceived the idea of using cerium chloride as a precipitant for the phosphorus, similar to the one suggested by him for the determination of phosphorus in vanadium steels. (This journal, January, 1913.)

The method used is as follows: Dissolve one gram of the bronze in 10 c.c. conc. hydrochloric acid and 5 c.c. conc. nitric acid in a tall-form 300 c.c. beaker. When solution is complete, add 150 c.c. of hot water, and 10 c.c. of a solution of cerium chloride (1 gram cerium chloride, 25 c.c. hydrochloric acid, 200 c.c. water). Now add a solution of one part ammonium hydroxide and two parts water, from a burrette, stirring continually until the solution has a greenish blue cast. This will require from 25 c.c. to 35 c.c. Now add 4 c.c. of acetic acid, and boil for five or ten minutes; remove from the hot plate and allow the precipitate to settle; this will require several minutes. Syphon off as much of the clear solution as possible, add 100 c.c. of hot water and again syphon. Repeat this washing six or eight times; with careful manipulation all but about 30 c.c. of the liquid can be decanted each time without disturbing the precipitate. After sufficient washing add 15 c.c. of nitric acid and 3 c.c. of hydrochloric acid

and heat until the precipitate has all dissolved. When solution is complete, cool, add 5 c.c. (1-1) ammonia, and precipitate the phosphorus.

By this method the writer has been able to have the phosphorus precipitated in duplicate on three samples in an hour. When this method is used the tin is determined on a separate sample either electrolytic, by titration, or from the combined oxides.

The following results were obtained on actual phosphorus-bronzes, and on bronzes to which a known amount of phosphorus was added.

---

## The Emissivity of Metals and Oxides

### I.—Nickel Oxide (NiO) in the Range 609 to 1300 C.*

BY G. K. BURGESS AND P. D. FOOTE

The object of the present investigation has been the determination of the monochromatic emissivity $E_\lambda$ and total emissivity E of nickel oxide NiO in the range 600 deg. C. to 1300 deg. C. This oxide forms a tough, smooth layer on the surface of nickel when subjected to high temperatures in air. Two methods were employed for the determination of the emissivity for red light: (a) that of microscopic melts and (b) a direct comparison by a spectrophotometer of the intensity of light emitted by the glowing NiO and by a black body at the same temperature.

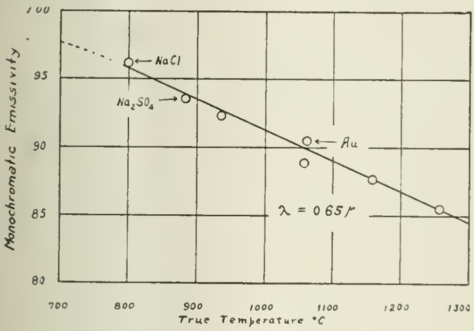

FIG. 1—MONOCHROMATIC EMISSIVITY ($\lambda = 0.65 \mu$) VS. TEMPERATURE

In the method of microscopic melts, minute specimens of NaCl, $Na_2SO_4$, and Au were placed on the oxide which was electrically heated until these substances melted, as observed with a microscope, and the "apparent" temperatures at the instant of melting were measured by an optical pyrometer. The relation between the true temperature of the oxide, the observed or apparent temperature, and the emissivity is expressed by:

$$\frac{1}{T} - \frac{1}{S_\lambda} = \frac{\lambda}{0.4343\, C_2} \log A_\lambda$$

where $T$ is the true absolute temperature, $S_\lambda$ the observed absolute black body temperature for a wave length λ, $c_2$ the Planck or Wien constant (14,450) and $A_\lambda$ the emissivity for a wave length λ.

In the spectrophotometric method, a nickel strip was folded, forming a wedge or V-shaped cavity, and electrically heated until a coat of the oxide was formed. It has been shown by Mendenhall that the radiation from the interior of a V-shaped cavity is closely "black." The ratio of the intensities of the outside and inside of the wedge, properly corrected for temperature gradient through the walls, gives at once the emissivity at any particular wave length and temperature. Determinations by this method agree with those by the method of microscopic melts, as is seen in Fig. 1. This curve represents the monochromatic emissivity, for $\lambda = 0.65 \mu$, as a function of the temperature. Over the range 700 deg. t o1300 deg. C., the emissivity decreases with increasing temperature.

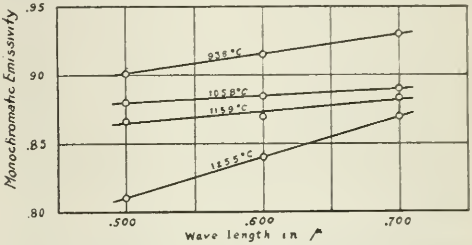

FIG. 2—MONOCHROMATIC EMISSIVITY VS. WAVE LENGTH

Fig. 2 shows the dispersion of the emissivity of NiO in the range $\lambda = 0.5$ to $0.7 \mu$ for the temperatures 938, 1058, 1159 and 1255 deg. C. Over this range of the spectrum the emissivity is found to increase with increasing wave length. The type of curves suggests the presence of an absorption band in the early infra-red, but one which is probably broad and not well defined.

The total radiation of NiO was investigated by means of twelve radiation pyrometers of the Thwing and Féry types. These instruments were sighted upon a strip of the electrically heated oxide. The apparent temperatures of the oxide for $\lambda = 0.65 \mu$ were measured by a Holborn-Kurlbaum pyrometer and these values corrected to true temperatures by means of the determinations on the monochromatic emissivity. Knowing the apparent absolute temperature, S. determined by the

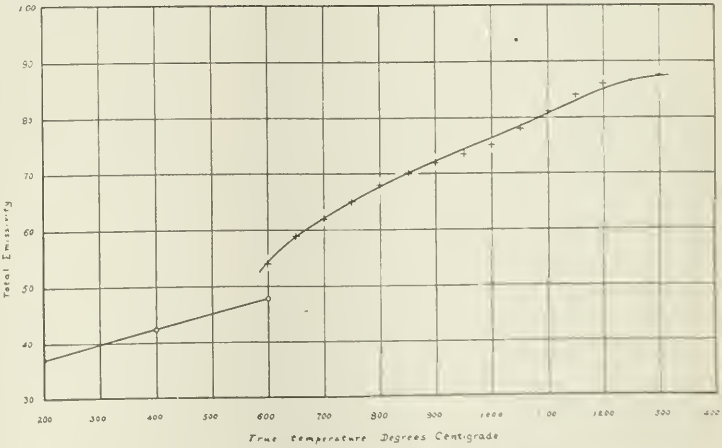

FIG. 3—TOTAL EMISSIVITY VS. TEMPERATURE

*The complete paper giving all observations and detailed description of apparatus will appear in the Bulletin of the Bureau of Standards.

radiation pyrometers, and the true absolute temperature, $T$, the total emissivity, $E$, may be computed from the relation $E = \frac{S^4 - T_0^4}{T^4 - T_0^4}$, where $T_0$ is the absolute temperature of the receiver.

Fig. 3 represents the total emissivity as a function of the temperature. The increase of emissivity with increasing temperature is very pronounced. In the range 700 deg. to 1200 deg. the increase is nearly linear with temperature. Obviously, this linear relation will not extend indefinitely, for the emissivity can not exceed 1.00 or become zero. The characteristic curve must therefore be bent at both ends. This departure from the straight line is apparent at 1200 deg. to 1300 deg. It is possible that the emissivity at still higher temperatures increases very slightly and gradually until the melting of the oxide may bring about a discontinuity in the curve. Somewhere below 600 deg. the curve must again change its slope, possibly becoming approximately parallel to the axis of temperatures.

The three points represented in Fig. 3 by circles are from the data of Randolph and Overholser. It is possible to extend our curve so that it will coincide with the 400 deg. and 200 deg. points determined by these investigators. The disagreement of the two curves at 600 deg., however, would indicate a systematic difference between the two sets of data.

The following table gives the true temperatures corresponding to the temperatures observed by (1) an optical pyrometer using red right ($\lambda = 0.65\,\mu$) and (2) by a total radiation pyrometer when sighted on nickel oxide.

| Observed temperature deg. C. | Optical pyrometer true temperature deg. C. | Radiation pyrometer true temperature deg. C. |

## Energy of Vaporization of Carbon

BY CARL HERING

The energy required to vaporize carbon, commonly called the latent "heat" of vaporization, does not seem to have been determined experimentally. It is sometimes very desirable to know it in analyzing the energy reactions in electric furnace processes, in which the cost of the energy is often an item of importance. One therefore has to resort to the less satisfactory method of determining it by calculation, at least approximately. The following is an attempt to do so on a basis which may possibly be new:

According to experimental determinations the energy set free when one gram molecule (28 grams) of CO is formed from one gram atom (12 grams) of solid C and one gram atom (16 grams) of gaseous O, is given in books as 26.1 kilogram calories. When one gram molecule (44 grams) of $CO_2$ is formed from solid C and gaseous O, the energy set free is stated to be 94.3 kg cal. When one gram molecule of gaseous CO is burned to gaseous $CO_2$, 68.2 kg cal are set free, this being of course equal to the difference between the other two, 94.3 — 26.1.

When solid carbon is changed into a gas, then the attraction of the molecules of the carbon which caused it to be a solid, has been overcome and the molecules have been separated far enough to make it a gas; this is true whether this gas is a true vapor of carbon or a gaseous compound of carbon. It takes energy to do this, and the amount required for the true vapor is usually termed the heat of vaporization. There seems to be no good reason why this should be materially different in amount when the gas is a compound of carbon like CO or $CO_2$ than when it is the pure vapor; the disruption of the molecules from each other is accomplished in either case. Let this energy be represented by $V$ in kg cal for the amount of carbon now involved, namely, 12 grams.

The energy for this physical change of state must have been supplied by the energy of the chemical union of solid C and gaseous O, hence the observed 26.1 effective kg cal of their union to CO is only the difference between the purely chemical energy and what might be called the purely physical energy. The real chemical energy is therefore $26.1 + V$. Similarly the real chemical energy of $C + O_2 = CO_2$ is $94.3 + V$. When CO is burned to $CO_2$ no energy of vaporization is involved, all the components being gases before and after the reaction. The energy involved in changes of volume against atmospheric pressure, may be neglected in the present discussion as being relatively quite small; moreover, it is often considered to be included in the figures for the latent heats.

These two numerical values together with $CO + O = CO_2 = 68.21$, are not sufficient to calculate $V$ from them. Prof. J. W. Richards in the *Trans. Amer. Electrochem. Soc.*, Vol. XIII, p. 451, estimates the latent heat of vaporization of carbon by calculation based on Trouton's statements, to be approximately 3808 calories per kilogram. But, like many other authors, he unfortunately omits stating whether these are large or small calories; there is no doubt, however, that kilogram calories were meant.

For the 12 grams of carbon now involved, the volatilization energy $V$, required in the combustion, would then be 45.7 kg cal. Hence the real chemical energy of $C + O = CO$ would be $26.1 + 45.7 = 71.8$; and of $C + O_2 = CO_2$, $94.3 + 45.7 = 140.0$. It will be noticed that when thus reduced to true chemical energies, the latter is almost exactly double the former, and the former is very nearly the same as the 68.2 for $CO + O = CO_2$. Changing the volatilization energy from 45.7 to 42.1 (only about 9 per cent) makes this relation exact; the true chemical energy of CO would then be 68.2, which is the same as found for CO + O; and that of $CO_2$ would be 136.4, which is exactly double 68.2.

While such an agreement may, of course, be merely a coincidence of no significance, yet on the other hand there is a good reason to believe that it should be so, as it would simply mean that, when reduced to *true* chemical energy, carbon develops exactly as much energy in combining with its first molecule of oxygen as it does in combining with the second one, and this would by no means be unlikely or irrational, but is even likely to be the case.

If the latter is true, then it becomes possible to deduce the true energy of vaporization of solid carbon very simply and directly from these two observed physical constants 26.1 and 94.3, in the way explained above. That for 12 grams then being 42.1 kg cal, the specific value would be 3510 kg cal per kg. This is only about 9 per cent less than Prof. Richards' calculated value 3808, which he himself gives only as an approximation. Berthelot, in his well-known treatise, does not give any definite value for the vaporization energy of carbon, but he states with positiveness that it is not less than 42.1 kg cal for 12 gr.; this is exactly the same figure as that given above.

Working backwards from this value by the same method as used by Prof. Richards to deduce it, brings the boiling point of carbon (namely, the temperature of the arc) down to 3387° C., which seems to agree even better with other determinations than the value assumed by him, 3700° C.

To further investigate whether it is a mere coincidence or whether it is likely to be a possible law, that the true chemical energy of each bond between like elements is the same, the writer has in the accompanying table deduced the true chemical energy between the bonds of carbon and hydrogen, as the known compounds formed between these two elements are far more numerous than between carbon and oxygen. Those here given are only those which normally are gases, so as to eliminate the unknown physical energies which must be set free when gaseous hydrogen contracts in forming liquid or solid compounds. They are furthermore limited to those whose energies of combinations have been determined by experiment, or possibly only by calculation, and have been published. In the formation of all of these compounds it is here assumed (although not always so stated in the books) that the original materials were solid carbon and gaseous hydrogen, hence that a physical change from solid carbon to a gaseous compound is involved in the reaction. The so-called "heats" of combination on which the present deductions are based, are probably not accurate and may in some cases even be quite inaccurate, more especially in the more complex quantities toward the bottom of the table; hence very close agreement cannot be expected in such an analysis as this.

These fourteen different compounds of C and H are arranged in this table in the order of the number of their atoms of carbon and hydrogen. The first column gives their molecular formula (which in some of the more complex cases may perhaps not be definitely known). The second column gives the energies of their formation from solid carbon and gaseous hydrogen, as given in reference books; the numbers in all the other columns except the last, have been deduced by the writer. The + and — signs mean energies set free or consumed, respectively.

The third column gives the physical energies consumed in the vaporization of the carbon, using the basic figure deduced above, namely, 42.1 kg cal per gram molecule (12 grams) of carbon. This is the only physical change considered for the first approximation. The important point at present is not so much the actual value of this constant, as the fact that it is taken to be the same for all.

The next column shows what the purely chemical energy must have been so as to have furnished the physical energy in the previous column, and the net balance given in the second column; these net balances are the algebraic sums of the figures in the third and fourth columns.

Having thus determined the first approximation to the true chemical energy, these numbers are then divided by the number of hydrogen atoms to see whether the energy value for each hydrogen atom is the same in the different compounds. These results are given in the fifth column, and it will be noticed that, at least for the simpler and better known compounds, there is a rather surprisingly close agreement, considering the crudity of the basic data and the following additional correction factors.

It will be noticed that the energy per H atom thus deduced grows larger as the number of atoms of carbon in the molecule increases; also, in each group, as the number of hydrogen atoms per molecule increases; hence it would be natural to suppose that it might increase as their product. This increase is as would be expected. More atoms are crowded into a molecule in the more complex materials. Such more crowded molecules mean physically that either there has been less expansion of the solid, or some contraction of the gas, or both; either means a gain of energy (physical). These gains mean that the physical energies in the third column are numerically less, and that the calculated, purely chemical energies are therefore less than those given in the first approximation in the fourth column.

TABLE.

| I | II | III | IV | V | VI | VII | VIII |
|---|---|---|---|---|---|---|---|
| | Kilogram Calories | | | | | | |
| | Per gram molecule | | | Chemical per H Atom | Molecular per Gr. Mol *e* | Second Approx Col V | Combustion Energy per Gr. Mol. |

| $C_4H_{10}$ | +35.0 | −168.4 | +203.4 | +20.3 | + 50.9 | +16.3 | 687.2 |
| $C_5H_{10}$ | + 7.3 | −210.5 | +217.8 | +21.8 | + 65.3 | +16.8 | 804.0 |
| $C_6H_6$ | −11.3 | −252.6 | +241.3 | +40.2 | +149.8 | +34.2 | 784.1 |
| $C_7H_8$ | − 5.4 | −294.7 | +289.3 | +36.2 | +127.3 | +29.3 | 933.8 |
| $C_8H_{10}$ | − 6.8 | −336.8 | +330.0 | +33.0 | +177.5 | +25.0 | 1084.3 |
| $C_{10}H_{16}$ | +12.2 | −421.0 | +433.2 | +27.1 | +189.2 | +17.1 | 1473.3 |

For the present purpose of analyzing the energy reactions only, it may be assumed that all the atoms of carbon were first separated by the energy represented by the latent heat of vaporization (third column) and then afterwards compressed or condensed again to the extent represented by the molecular formula in the first column; also that the hydrogen atoms, originally fully separated, have also been condensed to the indicated extent. Such condensations or contractions are exothermic; that is, they set free energy, and this energy, it is not unreasonable to suppose, should be greater the greater this condensation (which it will be seen from the table is the case), but according to what quantitative law is perhaps not yet known.

The sixth column shows what this physical energy of molecular condensation *e* would have to be in kg cal per gram molecule of the compound if the law above suggested is true, namely, that the true chemical energy (when separated from all the energy of physical changes) is a constant for each hydrogen atom with which the carbon has combined. If these energies could be calculated or measured, and were found to agree approximately with those in this column, it would establish this proposition and at the same time confirm the value for the energy of vaporization of carbon assumed in this analysis. The first value in the fifth column (+ 15.25) has in this first approximation been taken as a basis for calculating *e* because that compound contains the least carbon per molecule.

It will be noticed that the values of this extra energy *e* increase approximately in proportion to the product of the number of atoms of carbon and of hydrogen. This may again be a mere coincidence, but both the direction and the relative amounts are what one might expect, and that some energy would be set free by increasing the number of atoms in a molecule will probably not be questioned; it is claimed, for instance, that carbon vapor has double the latent heat of vaporization when monatomic than when diatomic.

Adjusting the purely chemical energies in accordance with this proposition concerning the energy *e*, gives as a second approximation for the hydrogen bond the figures in the seventh column, which it will be seen are in rather strikingly close agreement, excepting only some of the more complex molecules the constitution of which may perhaps not yet be definitely known. The agreement is now far better than in the fifth column.

In a further approximation the values of *e* should be added algebraically to the physical energy in the third column, in order to give the total physical energy involved; and they should also be subtracted arithmetically from the chemical energy in the fourth column, to give the true chemical energy; the algebraic sum of these new physical and chemical energies will then again give the observed net values in the second column.

It may or may not be a further coincidence that the purely chemical bond of oxygen is nearly the same for the combination with carbon as with hydrogen.

As a matter of interest the energies of combustion (presumably into $CO_2$ and $H_2O$, although not always so stated in books) are added in the final column. It will be noticed, and this may also be of significance, that when these compounds are arranged in this order, as distinguished from the order more generally used in books, they are also in the order of their combustion energy value, the only exception being again $C_6H_6$ (benzol) which is out of agreement in other columns also, hence is likely to be wrong; and either one of the two values of $C_3H_6$ (propylen and trimethylen), which, disagreeing with each other, cannot both be correct.

The above analysis is an illustration of the possible importance of more clearly distinguishing between the purely physical and the purely chemical reactions in energy equations, as was advocated in an article on this subject by the writer in the July issue of this journal, page 439.

The writer is indebted to Prof. G. A. Roush for some information concerning existing and non-existing data.

Philadelphia, Pa.

## Recent Chemical and Metallurgical Patents

### Iron and Steel

**Electric Steel.**—To Mr. **William R. Walker**, of the United States Steel Corporation, recently two interesting patents have been granted on electric steel processes.

The first patent relates to the manufacture of steel from iron which may be classified as to its phosphorus content between the grades commonly known as basic Bessemer iron (1.8 to 2.2%, P) and acid Bessemer iron (below 0.12%, P). The iron is first blown in acid converters of 13 tons capacity to remove the silicon and a portion of the carbon. The iron is only slightly oxidized by this partial blow. It is then transferred to an intermediate mixer of 125 tons capacity in form of a basic open-hearth furnace, so as to bring about substantial uniformity in the products of the several converters and to carry always a supply of hot metal for the subsequent treatment in the electric furnaces. In the mixer the phosphorus content is reduced to the point desired in the final product, while a portion of sulphur is incidentally removed and more iron is oxidized. From time to time portions of metal in the intermediate mixer are transferred to acid-lined electric furnaces of 25 tons capacity where the metal is deoxidized. The metal is then transferred to a final mixer in form of a ladle of 100 tons capacity with an acid lining and with or without electrodes or other heating means. A substantial quantity of molten metal is maintained in this final mixer so as to obtain a product uniform in carbon and other ingredients. The refined steel produced in this final mixer is then cast either directly therefrom or by transferring it first to a more convenient smaller casting ladle. Either in the electric furnace or in the final mixer or in both, deoxidizing additions of manganese and aluminium are made to the metal. The chief feature of this combination process is that the cost of the electric furnace treatment is considerably reduced. Not only does the intermediate mixer provide metal for a nearly continuous use of the electric furnaces but the cost of dephosporization in the mixer is low. The electric furnace is used for nothing but deoxidation for which purpose it is eminently fitted on account of its reducing atmosphere. Finally the use of an acid electric furnace means a substantial saving of expense, both first cost and repairs and other operating costs, and a larger tonnage per day than could be obtained with a basic lining. (1,086,003, Feb. 3, 1914.)

In Mr. Walker's second patent, which refers to basic-lined electric furnaces, it is pointed out that the object for using a highly basic slag in electric steel furnaces is to reduce to a minimum the sulphur content of the product. He has found, however, that by using a slag containing a comparatively high percentage of silica, the sulphur content may be reduced to practically the same extent as before and considerable economies are effected in the operation of the furnace and also an improvement obtained in the quality of the steel. Mr. Walker proposes to increase the quantity of silica in the slag in basic processes to such an extent that a part will be reduced and remain in the metal, at the same time keeping the percentage of silica so low that it will not cut the hearth to any substantial extent. As a good practical example is cited a slag made of silica 30 per cent and lime (approximately pure Ca O) 70 per cent, to which is added coke at least 5 per cent by weight of the combined silica and lime. This slag will also contain magnesia and alumina, which are derived from the furnace bottom materials and the lime additions. The process has various advantages. Slag of this composition is more fusible. The quantity of fluorspar may be reduced to little or none. The formation of fumes in the furnace is minimized. The silica roof of the furnace will last much longer. The process is of particular advantage in the manufacture of soft steel. The greater or less quantity of nascent silicon which enters the bath serves to purify it and in a way to make up in purifying effect for the lack of carbon in the bath. The silica in the slag may be so proportioned that the quantity of nascent silicon which enters the bath shall be only sufficient to have a purifying effect and shall not be sufficient to leave any appreciable percentage of silicon in the finished product. (1,086,489, Feb. 10, 1914.)

**Manufacture of Electrolytic Iron.**—To obtain high efficiency in the electrolytic production of iron deposits, **Anthelme Boucher** suggests the use of a high-current density. Ferrous salts may be used as electrolyte and to obtain a smooth surface, the electrolyte is stirred with air, whereby the ferrous chloride is changed into an oxychloride of iron. "This reacts on the hydrogen in bubbles adhering to the cathode, and thereby eliminates the cause of the bad quality of the deposits." The electrodes, therefore, are rotated. Besides the oxychloride, ferric chloride is also produced. To prevent the ferric chloride to be converted back into ferrous-salts the electrolyte is passed in a separate cell over iron shavings. The solution should become chestnut brown and not foaming. The higher the current density employed the greater must be the speed of the rotating cathode and the higher must be the temperature. At 1000 amperes per square meter the suitable temperature is 75 to 77 deg. C. The concentration of the liquid must be constant and be chosen according to its depolarizing power; it is maintained by adding fresh liquid to it. The greater the speed of circulation of the electrolyte, the lower will be the proportion of phosphorus. Air can be injected in varying quantities, forming basic salts for the depolarization. (1,086,132, February 3, 1914.)

**Manufacture of Iron.**—**Augustin E. Bourcoud**, of London, England, wants to reduce iron from its ore by means of gases. The $CO_2$ resulting is regenerated again. Comminuted or granulated ore and flux travel under agitation through a stream of CO and some $CO_2$, and the reduced metal is then melted in an electric furnace. Injurious moisture, organic and volatile impurities are eliminated by hot air, hydrogen is eliminated by coke in a regenerator, sulphuric gases by lime above 900 deg. C. Sulphur in metal is removed in the electric melting furnace. The furnace is arranged to utilize all waste heat; it controls temperature and composition of gases, waste products and charge. In Fig. 1 producer gas from *o* is burned in the stove inlets *n*. the gases leaving through chimney *d*. Air is highly heated in stove *a* and distributed to supply the producers *o*, to burn gas for heating stoves, while a third part passes through the inclined rotary heater *g* to the chimney *d*. The charge enters *g* in opposite direction, where it is dried. The hot producer gases then reduce it in the reduction furnace *h*. The gases, now rich in $CO_2$ are highly heated in stove *b* and regenerated with coke in *i*, heated again in *c*, desulphurized in *s* and used over again in furnace *h*. The reduced iron is then discharged into either electric furnace *k* or *k'* by slide valves. (1,086,133 and 1,086,134, February 3, 1914.)

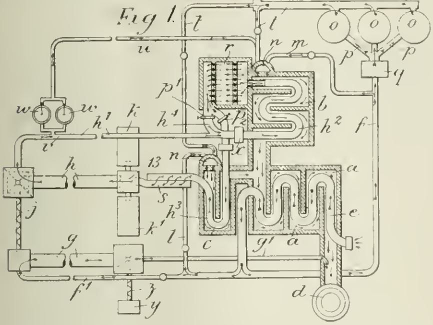

FIG. 1—IRON REDUCTION BY MEANS OF GASES

**Refining Steel.**—Low-carbon steel can be made or dephosphorized in an electric or open-hearth furnace by an oxidizing slag when adding manganese from time to time into the bath, according to a patent of **Axel Hethey**, of London, England. The charge should contain from 0.25 to 1.00 per cent Mn., which prevents a solution of iron oxide in the metal, yet oxidizes the phosphorus and removes also oxygen and sulphur. According to another feature of this process, the oxidizing slag may be left in the furnace and to prevent oxide being dissolved, the slag is stiffened with lime or dolomite, so that the heat can be finished with increased temperature to render pouring easier. (1,089,410, March 10, 1914.)

**Furnace Roof.**—A water-cooled flat roof, especially adapted for open-hearth furnaces was invented and patented by **Edwin E. Slick**, of Pittsburgh, Pa. Ordinary buckstaves support a series of water-cooled boxes, forming supports or girders. The bottom of said boxes has a dove-tail groove, co-acting with firebricks of similar shaped projections. The upper diagram of Fig. 2 shows how the remaining space 9 is filled with small bricks or mortar, allowing the firebricks being replaced independently. The lower diagram is a modified form, in which the recesses allow suspension by means of washers and bolts from the water-cooled boxes. (1,088,634, February 24, 1914.)

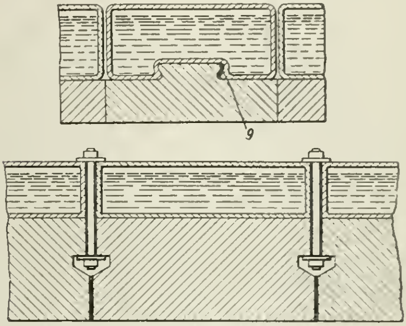

FIG. 2—FURNACE ROOF

**Reduction Without Smelting.**—Among the proposals to reduce iron and other oxide ores without resorting to smelting, is that of Mr. **Harvey C. Alford**, of St. Louis, Mo. His patented process consists in heating externally a charge of ore in a finely divided state, to a temperature below the point of fusion, mixing the heated ore with powdered coal, without access of air, and then agitating and heating this mixture in a suitable container to a temperature approximating 1000° F. The operations are carried out in revolving drums, the discharge of the first mixing with coal and entering the second. An excess of carbonaceous fuel is maintained to avoid the occurrence of reversible reactions between the reduced metal and any source of oxygen such as carbon dioxide. The product is reduced metal or sponge, mixed with the excess of fuel which may be removed from the metal in any suitable manner. (1,097,156, May 19, 1914.)

**Manufacture of Steel.**—According to a process of refining steel, whereby phosphorus, oxides, silicates and other impurities are removed, patented by Mr. **Albert Patton**, of McKeesport, Pa., metal that has been blown in the Bessemer converter, in which carbon, silicon and manganese have been reduced as low as possible, is treated as follows: Pour into an acid-lined intermediate receptacle, and from this into a basic-lined receptacle, care being taken to prevent the acid slag from entering the basic-lined receptacle. Materials for forming a basic slag are added to the latter before or during the pour. Phosphorus, being present in the Bessemer metal as $P_2O_5$, is absorbed by the basic slag. Manganese or re-carburizer can be added, if desired, in the basic-lined receptacle. (1,091,588, March 31, 1914.)

**Bessemer Converter.**—According to an invention of Mr. **Joseph V. Bretaud**, of Highland Park, Mich., the cost of construction and operation of a converter plant may be reduced by using converter shells comprising an upper and a lower section. Each section is removable from its support independently of the other, so that when the lining gives way in one part, it is necessary only to remove that section in which the break occurs. The removed section, having its lining exposed, cools rapidly and can be repaired quickly. The inventor claims that with this construction, two converters can produce the same number of heats otherwise obtained from three ordinary converters. (1,088,401, Feb. 24, 1914.)

### Gold and Silver

**Apparatus and Method for Filtering Slimes.**—A number of patents recently granted to Dr. Charles Butters, of Oakland, Cal., disclose his latest ideas in slime filtration, and particularly his methods of avoiding conflict with the ideas of other inventors regarding dislodgment of the filter cake from the fabric. Heretofore it has been the practice to effect dislodgment by air pressure applied internally to the leaf, and it has been assumed that such pressure was necessary to secure dislodgment in economical time. This application of compressed air has resulted in certain requirements in the construction of filter leaves, notably the use of outside strips fastened at intervals to the filtering medium, or stitching the two sides of the leaf together, for the purpose of preventing ballooning when internal pressure was applied. This manner of construction has resulted in reducing the available filtering area of the leaf, as well as weakening it and shortening its life.

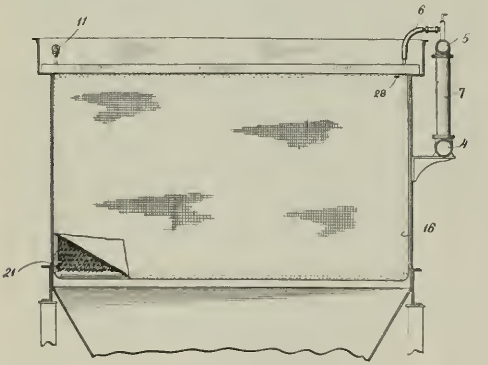

FIG. 3—NEW VACUUM FILTER LEAF

Mr. Butters has discovered that internal pressure is not necessary to the dislodgment of the cake, and that this operation can be accomplished by saturating the entire area of the filter medium with water, thereby destroying the adhesion of the cake. Water is applied internally, but not under pressure, and a relief valve is provided to permit the complete expulsion of air as the leaf fills with water. "It is understood that the cake may be, and preferably is, dislodged while the leaf is submerged in wash water. This means that there will be considerable hydrostatic pressure on the outside of the leaf. It has been found by experiment that the difference in specific gravity of the more or less dirty tank wash water and the relatively clean cake-dislodging water would be sufficient to maintain a column of the relatively clean water inside the leaf several inches higher than the level of the tank wash water, so that the relief valve (for expulsion of air) and the inlet for the cake-dislodging water may be several inches above the surface of the tank wash water without producing greater pressure inside the leaf than the outside pressure on the leaf."

By this means the external hydrostatic pressure may be balanced but can never be exceeded by the internal hydrostatic pressure, and yet the fabric may be moistened by water applied internally, and the cake easily dislodged. This system of treatment also makes it possible to use a lighter filter fabric and to dispense with bracing, stitching, etc., formerly used to prevent ballooning.

The construction of the filter leaf is shown in the drawing Fig. 2, in which a frame of pipe or tubing is covered with a bag of duck or other fabric. Inside the bag is a filler of cocoa matting to keep the sides of the bag apart when vacuum is applied. The lower horizontal member of the frame is perforated or slotted along its upper side, and is connected to a vacuum pump by means of the pipe 16 and flexible connection 6. The upper horizontal member also is perforated or slotted along its lower side, and connected with the air-relief valve 11. Plugs are placed in the frame at 21 and 28. The air-relief valve is of any kind that will prevent the ingress of air when the leaf is under vacuum, but will allow air to escape when the leaf is filled with water.

In operation, a cake is formed on the leaf, and washed in the usual manner. When it is ready to be dislodged, water is admitted to the leaf by way of pipes 4, 7, 5 and 6, filling the leaf from the perforations or slot in the lower horizontal frame-member. As the water rises in the leaf the air is expelled through the relief valve so that the water finally fills the leaf completely and saturates the fabric. The cake is automatically and rapidly dislodged. (1,100,217-18-19-20-21-22-23-67, June 16, 1914.)

**Cleaning Filter Leaves with Lactic Acid.**—The use of a solution of lactic acid to remove deposits of lime from filter leaves has been patented by Mr. **Paul F. Leach**, of Wollaston, Mass. The patent is assigned to Moore Filter Co., of New York City. The inventor states that a solution of lactic acid in the proportion of 1 lb. of the commercial product, which is of 22 per cent strength, to 25 lb. of water, gives satisfactory results. Heating the solution to about 150 deg. F. accelerates the dissolution of the lime. Cold solutions will cleanse the leaves in about an hour and hot solutions in half that time. The fabric is not injured in any way; its fibres remain soft and flexible, and are not shrunk by the action of the lactic acid. (1,101,639, June 30, 1914.)

**Apparatus for Precipitating Metals from Solution.**—According to the specifications of a patent granted to Mr. **Frank A. Ross**, of Spokane, Wash., and assigned to Chalmers & Williams, of Chicago Heights, Ill., the inventor proposes to precipitate, say gold-bearing cyanide solution by causing it to flow successively through a number of revolving cylinders containing solid precipitant in the form of aluminium. The cylinders are perforated, and mounted on hollow, perforated shafts in wooden tanks. The solution flowing into the first tank of the series fills the cylinder where it is acted on by the precipitant. It flows out by way of the perforated hollow shaft and thence into the next box where the operation is repeated. Electrodes may be placed in each compartment, the idea being that electrolytic action will aid in precipitation. (1,101,569, June 30, 1914.)

### Zinc

**Controlling the Formation of Zinc Dust in Smelting.**—Preheating the smelting charge before placing it in the retort, is the method proposed and patented by **Alex Roitzheim**, of Düren, Germany, for preventing or minimizing the production of zinc dust in the smelting of zinc ores. He states that zinc dust is formed mainly in the first three to six hours after charging the retorts, and mainly before the beginning of the reduction of the charge. This he ascribes to the fact that when the mixture is placed in the retorts in a cold condition, the reduction commences at the outer portions where the charge is in contact with the hot walls of the retorts. The zinc vapor there produced passes through the cold interior of the charge on its way to the condenser, and becomes suspended as zinc dust, entering the condenser as such. When the entire charge becomes heated, the zinc fume begins to condense as liquid. He therefore proposes to preheat the charge to a temperature of 600 deg. C., which is between the temperature at which reduction commences and condensation occurs. (1,100,490, June 16, 1914.)

**Electric Zinc Smelting.**—According to the specifications of a patent granted to Mr. **Heinrich Specketer**, of Griesheim-on-the-Main, Germany, one of the sources of difficulty in the electric smelting of zinc where the charge is used as a resistor, lies in the fact that the bottom of the charge becomes a better conductor than the overlying layers, due to the greater density of the former portion. This results in an uneven reduction of the mass. In order to obviate this difficulty Mr. Specketer proposes to use a rotable electric furnace in which the position of the charge can be shifted from time to time, thereby maintaining more even conditions of resistance and smelting. Electrodes are placed at each end of the furnace, one near the exit for fumes and gases and the other at the opposite end. Both electrodes extend over the whole inner end surfaces of the furnace and have their connections disposed 180° apart around the circumference of the furnace. (1,099,211, June 9, 1914.)

### Copper, Lead

**Separation of Copper from Nickel and Cobalt.**—Mixtures of minerals of copper, nickel and cobalt have presented difficulties in metallurgy that have not been wholly overcome. Mr. **Victor Hybinette**, of Fredericktown, Mo., recognizing the problem presented by this mineral combination, has invented and patented a process which he claims affords a successful method of treatment. "This ore consists of a mixture of chalcopyrite and linnæite or siegenite, with silica and dolomite as gangue. There are also present varying quantities of marcasite and galena. An average sample of this ore will analyze, chalcopyrite 10 to 20 per cent; linnæite 4 to 8 per cent; galena 1 to 6 per cent; marcasite 2 to 10 per cent; silica sandstone 50 to 70 per cent, and dolomite 10 to 30 per cent." If lead is present in sufficient quantity, the inventor prefers to remove it by ordinary wet concentration, after which he treats the residue according to the following method, which would be adopted if lead were not present in large quantities. The ore is ground to 10-mesh or finer, roasted to remove about one-half the sulphur which is present in the chalcopyrite and innæite and subject to magnetic treatment. Copper and cobalt minerals are removed; the tailing will contain some copper and nickel and all the lead, if the last was not removed as above stated. These can then be recovered by wet concentration. The magnetic concentrate, containing 12 to 20 per cent copper, 2 to 5 per cent cobalt and 2 to 5 per cent nickel, is then smelted to matte, roasted to remove all or practically the sulphur and leached with sulphuric acid. Copper will be dissolved and nickel and cobalt will remain in the residue. Little or no iron will be dissolved from this roasted matte. (1,098,443, June 2, 1914.)

**Filtration of Flue Dust from Furnace Gases.**—For the purpose of removing condensable metallic fumes and other solid matter from the furnace gases of lead and copper smelters, Mr. **Gilbert Rigg**, of Palmerton, Pa., proposes to use a device illustrated in Fig. 3. The patent is assigned to the New Jersey Zinc Co. The object of the apparatus is to provide a filter and condensing medium for the retention of solid matter carried in the furnace gas and to maintain the filtering medium in a condition for continuously performing its function. Referring to the drawing, A indicates a housing suitably supported and divided into compartments C, D and E by means of gratings consisting of a series of bars F of inverted V-shape and a series of flat bars G. Transverse rods I extend through the housing and are connected with rods K directly above the bars G. Mechanism for moving these rods I and connected rods K is shown at the left of the housing. The housing is further provided with hoppers P at the top and an outlet Q at the bottom. The gas to be filtered enters through the inlet R into compartments C, and the filtered gas takes its exit from compartment E through the outlet S.

The material resting on the gratings consists of coarse coal, coke, gravel, slag, stone, brick or the like. Accretions from the solid matter in the smelter fume build on the coarse material on the lower grating and form an efficient filter. When the accretions are so thick as to retard the draft, the mechanism is brought into operation, moving the rods K over the bars G, causing the accumulation to fall into the compartment below. At the same time an equal amount of fresh material is dropped from the upper grating. The operation of the mechanism may be arranged to be controlled automatically by a pressure regulator, or it may be left to the attendant who will regulate it according to the condition of the filter as indicated by the pressure. In some instances the reciprocation of the rods K may be made continuous. (1,095,676, May 5, 1914.)

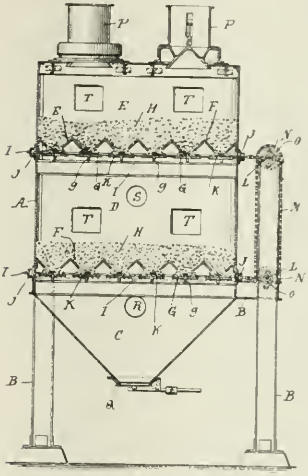

FIG. 4—FILTRATION OF BLAST FURNACE GASES

### Sintering Fine Ores

**Use of Addition Agent in Sintering.**—In the sintering process as devised by Mr. Ferdinand Heberlein, the mass of ore is exposed to the action of a current of air passed upwardly through the charge. A small percentage of the mass is not sintered, and in the case of agglomerating very fine dust it may happen that a considerable quantity may remain unsintered. To oversome this tendency Mr. **Edmond A. Preteeille**, of Nantes, France, proposes the addition of a salt, such as ferrous sulphate, to the charge, wetting the latter with a strong solution of the salt. It is his idea that the moisture thus added will be retained in the mass longer than if water only is added and that the salt will exercise a cementing effect on the fine particles, holding them together until they can be sintered by the heat of combustion. In the case of iron ore it would suffice to add sulphuric acid, which would form iron sulphate with part of the ore. In the case of iron sulphate solutions, 10 to 15° Be. has been found a suitable concentration. (1,096,054, May 12, 1914.)

**Improvement to Dwight-Lloyd Sintering Machine.**—Mr. Eugene H. Laws, superintendent of the Ohio & Colorado Smelting & Refining Co. at Salida, Col., has patented an improved construction of the sintering machine made by the Dwight & Lloyd Sintering Co., New York. In machines of this type a continuous traveling grate of pallets passes over a suction box for the purpose of inducing a down draft through the charge contained in the pallets. The edges of the pallets rest directly on the edges of the suction box and the transverse portions of the pallets drag over dead plates at the ends of the suction box, in order to prevent air entering the box otherwise than through the charge on the pallets. It so happens, however, that the wear on the edges of the pallets is much greater than on the transverse portions, with the result that eventually the transverse portions occasionally engage and tear the dead plates and strain the driving mechanism. Mr. Laws provides an adjustable support for the pallets as they pass over the suction box, whereby each pallet is carried in close proximity with the edge of the box, but out of wearing engagement with the edges or dead plates. (1,097,592, May 19, 1914.)

### Roasting Furnaces

**An invention relating to the air-cooling** of the central rotatable shaft of furnaces of the superimposed-hearth type, such as the Herreshoff, is patented by Mr. **Edward J. Fowler**, of San Francisco, Cal. The patent is assigned to the General Chemical Co., of New York City. Fig. 5 shows a cross-section of the shaft. It consists of a number of superposed sections fastened together by means of bolts. Concentric with the outer cylindrical wall, 3, is an inner cylindrical wall, 4, the two being held separate by radial ribs, 5. This structure forms an axial passage, 6, separated from and surrounded by an annular passage 7. Rabble arms used in connection with this shaft are hollow, and are divided into two interior passages by means of a longitudinal rib. When the arms are attached to the central shaft, one of the passages is in conjunction with the axial area, 6, and the other with the annular area, 7. Hence air passing up through the inner area of the central shaft is deflected through the opening 10, passes through the rabble arm and returns to the shaft by opening 9, and thence to the atmosphere. (1,100,426, June 16, 1914.)

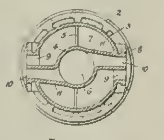

FIG. 5 — AIR-COOLED FURNACE SHAFT

**An air-cooled rabble arm** for use in roasting furnaces is patented by Mr. **Utley Wedge**, of Ardmore, Pa. It is shown partly in plan and horizontal section in Fig. 6. The rabbles or blades, 4, are cast integral with the arm. On the back of the arm and integral with it are helical ribs, 5. Both the blades and ribs are hollow and connected interiorly, so that there is a continuous passage from the blade at the outer end of the the arm to the one at the inner end. The rabble arm, 1, also is hollow, and communicates at its outer end with the hollow passage in the blades. By this construction it is possible for a current of air to flow from a passage in the central shaft to which the arm is attached, through the arm and back through the blades and thence to the air. (1,100,461, June 16, 1914.)

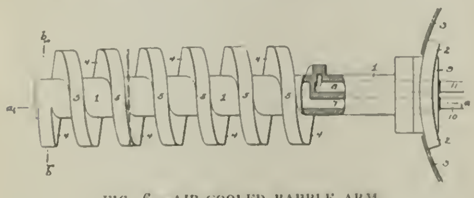

FIG. 6—AIR-COOLED RABBLE ARM

### Electric Furnace Construction

**Calcium Cyanamid.**—Mr. Walter S. Landis, of the American Cyanamid Co., of Niagara Falls, N. Y., produces calcium cyanamid in apparatus shown in vertical and horizontal cross-section in Fig. 7. 1 is a furnace lined with refractory material and provided with a lid 7. Inside the furnace there is a foraminous vessel 2 with holes of ¾ or 1 inch diameter covered inside with a textile fabric to prevent the carbide from falling out. The nitrogen gas is admitted through 11 into the annular space between the outer furnace wall and the inner vessel and enters into the inner vessel through the open top and through the holes in the sides and bottom. In construction c there is also a central hole provided for the passage of the nitrogen gas. 3 and 4 are a number of carbon resistors heated electrically to produce the desired reaction. Their connections 12 to the leads 5 and 6 are made of large diameter to heat them to a lower temperature and prevent their destruction by impurities in the nitrogen gas. 15 and 16 indicate the proceeding zones of reaction. With this construction the life of the resistors is very much prolonged. Further, with several resistors the reaction is much quicker than with a single one. (1,103,060, 1,103,061, 1,103,062, July 14, 1914.)

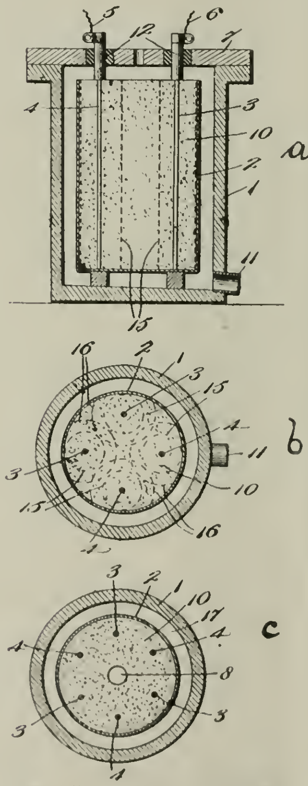

FIG. 7—CALCIUM CYANAMIDE FURNACE

**Electric Furnace.**—The Rennerfelt furnace was described in some detail in our April issue, page 275. A patent has now been granted to Mr. **Ivar Rennerfelt** for the principal feature of the furnace, namely, the arrangement of the electrodes. The second claim refers to "the method of generating heat by means of electric arcs consisting in passing two-phase currents along and between two opposing electrodes to the end of a third electrode at right angle to and symmetrically located between the first-named electrodes so as to cause an electric arc to burn between the ends of all the electrodes, strongly deviating away from the ends of the electrodes in the direction indicated by the symmetrically located electrode." (1,103,379, July 14, 1914.)

**Abrasive Compounds.**—A patent has been granted to **Thomas B. Allen**, of the Carborundum Company of Niagara Falls, N. Y., for the production of artificial garnet, an abrasive, by melting gradually 2240 lb. of calcined magnesia, 1493 lb. of alumina and 2760 lb. of silica. The molten mass is cooled slowly by insulation with some charge and when solid is removed at a temperature of 1200 to 1500 deg. C. and crushed while cooling with water to prevent dissociation. Similar compounds can be produced of the form $3R'OR''_2O_3 3SiO_2$, where R′ is calcium, magnesium or ferrous iron and R″ is aluminium, ferric iron or chromium. (1,087,705, February 17, 1914.)

**Electric Furnace.**—**Bayard Guthrie** and **Joseph P. Karch**, of Pittsburgh, Pa., have invented a combined electric arc and resistance furnace. The crucible 5 is supported and insulated by fire brick from the bottom plate. The surrounding bricks have a pair of chambers 11, separated by a refractory partition 12-12 to prevent arcing between the electrodes and to hold the crucible when tilting. The electrodes 13-13 fit snugly to the crucible bottom and flare at the top, the space between is filled with broken carbon 14 to break up the electric arcs between electrodes and crucible. The electrode lugs 13′ connect with copper electrodes and cables and an arrangement to adjust and hold the crucible by means of the electrodes. The heat is concentrated at the crucible top. This furnace is particularly adapted for direct or single-phase alternating current. The spout is so arranged as to discharge the metal direct into the center of a swinging mould, and touching its side walls. (1,086,164, February 3, 1914.)

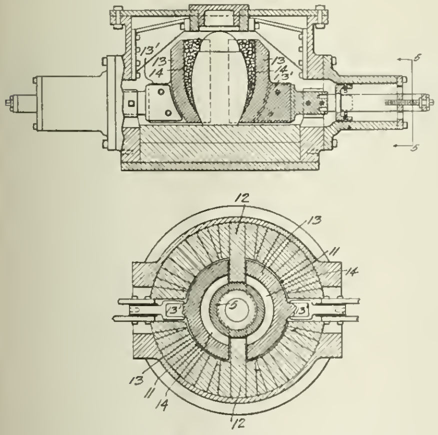

FIG. 8—ELECTRIC MELTING FURNACE

**Electrodes.**—The fact that the energy losses through heat conduction in the electrodes of electric furnaces exceed those caused by electric resistance is made the object of a patent granted to Dr. J. W. Richards, Bethlehem, Pa. The electrodes are built with gaps extending inward in different shapes. These gaps are either left as open spaces or are filled with material of low heat conductivity and thus lengthen the path of heat currents to the outside of the electrode. For example, it is possible to effect a large saving in electric energy by reducing the heat conductance 25 per cent., even though the electric conductance is thereby diminished 50 per cent. (1,088,296, February 24, 1914.)

**Protective Coating for Electrodes.**—The production of a coating of titanium nitride on furnace electrodes and other refractory materials is patented by Mr. **Samuel H. Fleming**, of Cleveland, O., and assigned to the National Carbon Co. of the same place. Titanium nitride is stable at high temperatures, is non-porous, tough and hard, and otherwise possesses qualities that make it valuable as a protective coating for substances that are subjected to very high temperatures in an electric or other furnace. In order to form the coating a mixture of rutile and some binder is pressed on the article to be coated, which is then baked at a high temperature in the presence of nitrogen. Owing to great affinity of titanium for nitrogen, the former is converted into nitride. A first coating of titanium carbide may be desired, as this substance wets carbon and enters the pores of its exterior surface and forms a perfect union with the carbon. This may be formed by applying a mix of titanium and carbon and heating with exclusion of air, forming titanium carbide. After the coating of carbide is formed the article may be heated in an atmosphere of nitrogen, thus converting part of the carbide into nitride. This latter conversion may be stopped before all of the carbide has been changed, if an inner coating of carbide is desired. (1,098,794, June 2, 1914.)

**Aluminium Nitride Lining for Furnaces.**—In order to overcome the great difficulties encountered in forming suitable linings for furnaces in which temperatures of, say 2000° C. are employed, Mr. **Ottokar Serpek**, of Paris, France, proposes the use of aluminium nitride. It possesses the property of being easily agglomerated and can be molded into various forms by using a binder such as sodium silicate. Such material resists the corrosive action of many chemical substances and may be advantageously used in industrial furnaces of different kinds. (1,099,131, June 2, 1914.)

### Phosphoric Acid

**A method of producing phosphoric acid from phosphate rock has been patented by Mr. Frank S. Washburn**, president of the American Cyanamid Co., Nashville, Tenn. The process disclosed is an excellent illustration of the possibility of bringing about chemical reactions at temperatures obtainable only in the electric furnace, and of the economic value of a combination of fuel and electric furnaces in commercial operation.

The chemical basis of the operation is the displacement of phosphoric acid from its compounds by means of silica. It is found, however, that the replacement is far from complete at temperatures obtainable in fuel furnaces, say 1400 deg. C. On the other hand, if an electric furnace be used, it is possible at higher temperatures to greatly increase the yield of phosphoric acid, and if coke be added to the smelting charge, the evolution of phosphorus can be made almost quantitative. Nevertheless, the cost of electric energy is too great to permit of carrying out the process economically. Thus, phosphate rock contains from 10 per cent to 20 per cent of calcium carbonate. The carbon dioxide can be driven off from this compound by the heat evolved in burning from 0.012 to 0.025 ton of coal per ton of rock, whereas it would require from 200 to 300 hp-hr. of electrical energy for the same purpose. With coal $3 per ton and electricity at $15 per hp. year, the comparison of cost is as 7½ and 15 cents, respectively, are to 40 and 80 cents.

respectively. The heat in the slag, per ton of rock charged, is equivalent to 1600 hp-hr., or $3.20 worth of electrical energy; while coke required for heating the charge is worth only $2. Thus a combined process may be more economical than the electrical alone. Phosphate rock mixed with silica and a suitable fuel can be smelted in a small blast furnace, producing a slag which can then be further heated in an electric furnace, with coke added to complete the reduction of phosphorus. Mr. Washburn has further demonstrated that by the use of very rich oxygenated air, which is conveniently obtained as a by-product from a liquid air plant, he can get very fusible slags that can be tapped from the blast furnace without difficulty.

The gases evolved from both shaft and electric furnaces are led to a common oxidization chamber, and any unoxidized phosphorus is there condensed by absorption in water or ammonia. By the use of a combination of fuel and electric furnaces, it is possible to obtain an almost complete extraction of phosphorus from the rock, with an expenditure of electrical energy less than half that required by an electric furnace alone. Slags of 45 per cent silica offer no trouble in the shaft furnace when enriched air is used. (1,100,639, June 16, 1914.)

### Electrolytic Processes

**Sodium Hydroxide and Hydrochloric Acid from Brine by Electrolysis.**—In a patent of the late **Eugene A. Byrnes** a diaphragm cell is proposed, divided up into a series of compartments containing alternately brine solution and water. In Fig. 9 the compartments 1, 3, 5 contain NaCl solution, the compartments 2 and 4 contain $H_2O$; 1 contains the anode and 5 the cathode. The partitions between the successive compartments are used as bipolar electrodes. They may consist, for instance, of wire gauze, covered by porous diaphragms. At the partition between 1 and 2 the Na cations from 1 and the OH anions from 2 come together and form Na OH which is drawn off. At the partition between 2 and 3 the H cations from 2 and the Cl anions from 3 come together and form HCl which is drawn off. The bipolar electrodes need not be inert as the electrode between 1 and 2 may consist of oxidized copper and the electrode between 2 and 3 of lead; in that case the copper electrode is oxidized by the hydroxyl and again reduced by the sodium ion with the production of sodium hydroxide, while the lead electrode is chloridized and again reduced by hydrogen with the production of hydrochloric acid; these products are washed out of the cell by water. The inventor proposes to short-circuit the electrodes at each side of the compartments 2 and 4 as indicated by the dotted lines 12. "The current then shunts around the bodies of water or other electrolyte in these intermediate compartments. The sodium and chlorine set free in the electrodes, however, with the intermediate body of water, constitute a voltaic cell, the hydroxyl of the water oxidizing the sodium while its hydrogen combines with the chlorine." (1,102,209, June 30, 1914.)

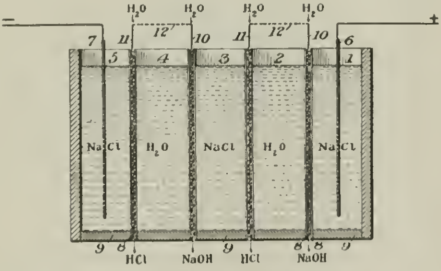

FIG. 9—SODIUM HYDROXIDE AND HYDROCHLORIC ACID FROM BRINE

## London Notes

### The Iron and Steel Institute

The autumn meeting of this Institute will be held in September in Paris in the Hall of the Comitè des Forges. Visits to the Basilica of St. Denis and to the works of the Compagnie des Metaux, as well as to Nancy for the purpose of inspecting the metallurgical works and mines, have been arranged.

### The Institute of Metals

The autumn meeting will be held on September 10 and 11 at Portsmouth. Arrangements have been made for inspections of the docks and of the works of Messrs. Samuel White & Co., at Cowes.

### The Congress of Mining, Metallurgy, Engineering and Economical Geology

The sixth meeting of this congress will be held in London next year and will extend from July 12 to 17. Each of the four sections will conduct independent proceedings.

### Market Prices—June, 1914

| | £ s. d. |
|---|---|
| Aluminum ingots, ton lots | 85. 0. 0 |
| Alum lump, loose, per ton | £5.5.0 to 5.10. 0 |
| Antimony, Star Regulus, ton | £26.15.0 and 27. 5. 0 |
| Borax, British refined crystal, cwt | 17/6 to 18. 6 |
| Copper sulphate, ton | 21. 0. 0 |
| Caustic soda, 70%, ton | 10. 0. 0 |
| Copper ore, 10% to 25% unit | 10/3 to 10. 9 |
| Ebonite, red., lb | 1. 6 |
| Hydrochloric acid, cwt | 5. 0 |
| India rubber, Para, fine, lb | 2. 9½ |
| Mica in original cases, medium | 3 6 to 6. 0 |
| Petroleum, Russian spot, gal | 9¼ |
| Quicksilver (Spanish), bottle | 7. 0. 0 |
| Sal Ammoniac, cwt | 2. 2. 0 |
| Sulphate of ammonia, ton | 10.15. 0 |
| Sulphur, recovered, ton | 5.10. 0 |
| Shellac, cwt. | 3. 4. 6 |
| Platinum, oz., nominal | 9. 5. 0 |
| Tin ore, 70%, ton | £82.0.0 to 84. 0. 0 |
| Zinc, Vieille Montagne | 25. 2. 6 |

Copper opened at £63 and declined till the 8th, £61.10.0, then recovered to £62 (11th), and again fell away to £61.5.0 (17th), and after a slight recovery (18th) to £60.1.3 (26th), showing slightly better on the next few days and closing £61.

Tin opened at £142 and was uneven over the first fortnight between the limits of £137 and £140. On the 16th it went lower, £137,15.0, but hardened slightly on the 23d to £139.7.6. A larger drop brought it on the 25th to £135.5.0, but closes slightly stronger £140.5.0.

Haematite opened at 61s. and has remained quite steady at this price.

Scotch pig opened 57s. 3d. and has been rather weak, showing 57s. 3d. on the 4th and 57s. 1½d. on the 16th, to which prices after recovery to 57s. 6d. on the 9th it again dropped on the 26th, declining to 57s. on the 29th.

Cleveland opened at 51s. 6d. and declined slowly to 51s. 1½d. on the 17th, and again, after slight recovery on the 25th, continuing downward to 51s. on the 29th and closing same price.

Lead opened £19.10.0 and reached £19.17.6 on the 4th, afterward rather lower, but again stronger on the 15th and rose to £20 by the 19th, after which it declined, reaching £19.5.0 by the 29th, but better at the close £19.10.0.

# Synopsis of Recent Chemical and Metallurgical Literature

## Iron and Steel.

**Tilting Open-Hearth Furnaces.**—A very interesting series of experiments has been carried out at Witkowitz, Austria, to compare the efficiency of the Talbot furnace with the Wellman tilting furnace and the stationary 69-ton basic open hearth. Dr. Schuster, the general manager of the Witkowitz Iron and Steel Works, gave a detailed account before the semi-annual meeting of the German "Verein deutscher Eisenhüttenleute" of the requirements of these works and of the considerations and deliberations preceding the final decision to build a new open-hearth plant. This plant was to be big enough to take care of their rolling mills and forging presses, capable of extension and yet flexible enough to allow a change of processes in case one or the other of the new furnaces should be no success.

So far England and America had been the pioneers of the tilting open-hearth furnace for continuous operation, whereas continental Europe, aside from a few unfortunate trials, showed no inclination for the Talbot process. As a matter of fact, the pig-iron-ore process promised to be the most economical under the local conditions and circumstances. And although two German experts who had investigated every English Talbot furnace by order of the company came to the conclusion that, only under certain restrictions, it would be advisable to use this process, Dr. Schuster decided to build two Talbot furnaces of 300 tons capacity each, three stationary 60-ton basic furnaces and one 60-ton Wellman furnace, the latter one in order to compare stationary and tilting furnaces of equal capacity. One of the Talbot furnaces was to serve a heatable mixer as the blast furnaces are at a distance of 1.3 miles from the steel plant, and the other should perform the same work in case the experiments should fail. This, however, did not happen, the new installations proved to be most successful and the extension of the plant is planned with Talbot furnaces. It also contains two electric furnaces, one of 2-ton capacity for melting ferromanganese, the other a 6-ton furnace for special brands of steel.

When working with 5 per cent of scrap in the Talbot, 13 per cent in the Wellman, and 25 per cent in the ordinary open hearth, the first cost of the three furnaces compares 1659:1259:1000. Figured per ton of product, however, this proportion is reversed and reads: 882:1070:1000, which shows the superiority of the Talbot furnace as to cost of erection. With pig iron containing 1.1 per cent of phosphorus, 1 ton of steel is produced in the three types in the same order of rotation in 4 min. 30 sec., in 7 min. 12 sec., and in 8 min. 30 sec. The metallic iron reduced from the additions of ore is 86 per cent, 80 per cent and 78 per cent respectively, and every quality of steel required is produced as reliably as in the stationary furnace.

Those present at the meeting were provided with extensive maps, tables and cost sheets showing the advantages of the combination as worked out for the special requirements at Witkowitz. They are too widely different from American conditions to be treated in detail here. Those familiar with the art will be interested to know that contrary to the prevailing tendency in building the furnaces a very limited use of water-cooling devices has been made and air cooling applied wherever possible.

During the discussion of the paper it developed that the Königshütte in Upper Silesia, for a few months, has had tilting open-hearth furnaces, a similar process being in operation of which little was known; the results obtained were so far very similar to those cited above. When speaking at the subsequent banquet, Dr. Schuster remarked that he had been more liberal than customary among the members of this society, in communicating his experiences for the common benefit of all, and hoped that his example would be followed by many successors.

## Gold and Silver

**Resistivity of Pure Silver, Solid and Molten.**—In a paper published in the *Journal* of the Franklin Institute, July, 1914, Dr. Edwin F. Northrup announces the results obtained in determining the resistivity of pure silver at temperatures between 20 deg. C. and 1340 deg. C. The silver used was very pure, being part of the supply used by Prof. G. A. Hulett in his study of the silver voltameter. For determining the resistivity between 20 deg. C. and 60 deg. C., the author used soft drawn wire, and oil-bath, mercury thermometer and Kelvin double bridge. The same silver was then used in a container of magnesite 40 parts and alundum 60 parts. The results were not checked, partly for lack of time and partly for the reason that the author's previous experience with the method makes it seem improbable to him that any serious errors have crept in. The table below gives the results of the determination. At the moment of fusion the resitivity suddenly increases from 5.5 to 16.6 microhms. The measurement was not carried to higher temperatures on account of failure of the thermocouple, due to opening of its circuit.

| Degrees Centigrade | Microhms per Centimetre | Ratios, $\rho t/\rho t_1$ | Remarks |
|---|---|---|---|
| 20 | $1.65_9$ | | |
| 60 | $1.90_6$ | | Increase per 100° C = 0.60 microhms |
| 960.5 | 8.4 | | Silver solid. |
| 960.5 | 16.6 | $\rho m/\rho s = 1.98$ | Silver molten. |
| 1000 | 17.01 | | Temperature coefficient calculated from 1000° C = .00069 |
| 1100 | 18.19 | | |
| 1200 | 19.36 | | |
| 1300 | 20.54 | | Increase per 100° C = 1.177 microhms |
| 1340 | 21.01 | | |

## Copper

**Proposed New Converter and Converter-Smelting of Ores.**—In the June, 1914, *Bulletin* of the American Institute of Mining Engineers, Mr. Herbert Haas publishes a long article describing the construction and proposed operation of a new type of copper converter, in which it is proposed to extend the matte-bessemerizing process to the direct reduction of fine pyritic ore. Converter-smelting is not new, having been practised to some extent at Great Falls and Cananea; but Mr. Haas makes some novel proposals which are intended to widen the scope of the process. His paper is too long to present in more than a very brief abstract.

The general premises on which the author makes his proposal are as follows: The cost of copper converting is now about $5 per ton of copper, or $2 per ton of 40 per cent matte. If further economy is to be attained a process must be adopted which will be cheaper than the present established practice of combined blast-furnace smelting and bessemerizing operations. The author explains that his proposed process will not displace existing methods, for converter-smelting is limited to the treatment of ore containing sufficient iron and sulphur to furnish the heat required to produce and sustain the smelting and bessemerizing temperature. The tonnage of concentrate that can thus be smelted depends chiefly on their iron and sulphur contents; a decrease in these two constituents in the concentrate requires an increase of them in the matte of the charge. Thus the matte should be low in copper and high in iron and sulphur, in order to furnish the requisite heat to smelt the more silicious concentrate, which would be high in copper but low in iron. The copper concentrate would then take the place of silicious flux to slag the iron in the matte.

As the rate of smelting and the elimination of iron and sulphur depend on the rate at which air is blown into the charge, Mr. Haas has given attention to the design of a converter-smelter that would provide larger volumes of air than are now required. Further, in order to gain technical efficiency the operation must be carried out in such a way as to allow no free oxygen to be discharged in the waste gases. Finally, the air should be used at as low a pressure as possible to reduce the cost of compressing.

Mr. Haas discusses the development of copper converting, and then describes his proposed converter. Briefly, it is a vertical type, bottom-blow converter with elevated tuyere bottom. The shell is lined with magnesite bricks. The most radical departure is the proposed use of a large number of tuyeres of small cross-section, confined to a central area in the converter bottom. Tabulated data are given showing an example of blowing a charge in such a converter. The smelting of fine pyritic ore or concentrate would be accomplished by blowing it into the charge with the compressed air.

The author discusses the air requirements for converting; the cost of power to furnish air, and the thermo-chemistry of the converting process.

### Magnetic Separation of Minerals

**The Ullrich Magnetic Separator.**—An article by Mr. W. Mewes in the *Mining & Engineering Review* (Australia) for May and June, 1914, describes the construction and method of operation of the Ullrich magnetic separator for both wet and dry work, and gives the results of tests. The Ullrich machine has stationary poles disposed about an annual support, and an annular armature rotating above them. Magnetic fields are generated in the intervening space. The armature is divided into a number of concentric rings of V-section, creating in each magnetic field as many zones of action as there are rings to the armature. Ore may be fed either wet or dry, but different constructions are used to meet the two different conditions. The following table gives some practical results obtained with the machines.

| Ores | Content, per Cent | Non-magnetic Product, per Cent | Magnetic Product, per Cent | Recovery, per Cent |
|---|---|---|---|---|
| Tin-tungsten | 30 $WO_3$ | 3 $WO_3$ | 68 $WO_3$ | 90 $WO_3$ |
| | 32 Sn | 62 Sn | 4 Sn | 95 Sn |
| Tungsten conc | 62 $WO_3$ | 10 $WO_3$ | 72 $WO_3$ | 97 $WO_3$ |
| | 3 Bi | 12 Bi | 0.15 Bi | 95 Bi |
| Tin, ilmenite | 10.61 Sn | 66.83 Sn | 0.03 Sn | 99.5 Sn |
| Spathic zinc | 15.9 Fe | | 30.1 Fe | |
| | 3.8 Mn | | 8.2 Mn | 75.2 Mn |
| | 27.8 Zn | 49 Zn | 2.5 Zn | 92.0 Zn |
| Spathic copper | 38.9 Fe | | 39.8 Fe | 68 Fe |
| | 1.04 Cu | 3.97 Cu | 0.13 Cu | 88 Cu |
| Hematite | 37.31 Fe | | 65.32 Fe | 80 Fe |
| | 0.238 P | | 0.025 P | |
| Roasted spathic iron | 37.2 Fe | | 48.1 Fe | 93.5 Fe |
| | 6.9 Mn | | 8.5 Mn | 89.5 Mn |
| Blast furnace dust | 43.0 Fe | | 57.3 Fe | 91.1 Fe |
| | 0.17 P | | 0.20 P | |

### Crushing and Grinding

**Grading Analyses by Elutriation.**—In reply to discussion on his paper on this subject before the Institution of Mining & Metallurgy, Mr. H. Stadler makes further remarks in *Bulletin* 117 regarding the usefulness of this method of making physical analyses of the finest portion of crushed ore. In view of the policy of fine grinding now in vogue in cyanidation, and of the losses attending the concentration of slime from base-metal ores, the author believes that elutriation should be more widely used for making grading analyses. The method of elutriation begins where screening stops, and besides being more accurate, it is in accord with practical operating conditions, as the handling of slime pulp consists almost exclusively of hydraulic methods.

"We are too easily inclined to consider slime as a definite product, yet the difference between one slime pulp and another may be just as great as between a 10 and 1000-mesh battery pulp. A percentage of moisture or a flow-velocity suitable for one slime pulp may be disastrous to another. The fact that the slimy portion of the ore is responsible for over 80 per cent of the total losses sufficiently warrants a closer investigation by the method of elutriation, which would certainly be a great help in tracing the causes of these losses, and a guidance for the introduction of possible improvements."

The proper operation of hydraulic classifiers can be accomplished only by correct dimensioning, and this, in turn, is involved with the velocity of the rising current of water which carries over the particles of desired size. From this empirically determined velocity and the flow quantities, expressed in fluid tons, the required classifying area may then be calculated by the following formula, in which 16.2 is the conversion factor from the metric to the British standards.

$$\text{Classifying area in sq. in.} \quad \frac{\text{Fluid ton per 24 hr.} \times 16.2}{\text{Velocity in mm. per sec.}}$$

The following example is given for calculating the diameter of a circular tube mill classifier, by which a 64-mesh battery pulp of 75 per cent moisture is to be classified into a thick underflow of 30 per cent moisture containing solids + 120 mesh, and on overflow containing the — 120 mesh portion:

**Intake**

| Mesh | Weight | Dry Solids |
|---|---|---|
| + 120 | 66 2/3 | 300 tons |
| — 120 | 33 1/3 | 150 " |

| | |
|---|---|
| 450 tons of solids, sp. gr. 2.7, | 166.6 fluid tons |
| water (75% of inlet pulp), | 1350.0 " " |
| | 1516.6 " " |

**Overflow**

| | |
|---|---|
| — 120 mesh, 100%, 300 tons, sp. gr. 2.7, | 55.5 fluid tons |
| water (89% of overflow pulp), | 1221.5 " " |
| | 1277.0 " " |

**Underflow**

| | |
|---|---|
| + 120 mesh, 100%, 300 tons, sp. gr. 2.7, | 111.1 fluid tons |
| water (30% of underflow pulp), | 128.5 " " |
| | " " |
| | 239.6 " " |

The velocity of water effecting a separation similar to that made by 120-mesh screen is 10.08 mm. per sec. Hence:

$$\text{Classifying area in sq. in.} = \frac{1277 \text{ fluid tons} \times 16.2}{10.08 \text{ mm. per sec.}} = 1060 \text{ sq. in.}$$

equivalent to the area of a circular classifier of, say, 3-ft. diameter.

The method of classifying by elutriation is based on different principles than sizing by screens. Neither is an accurate means of measurement, but each has its sphere of usefulness. While sizing by screens is suitable for the study of mechanical efficiency of grinding machines, grading elutriation is more trustworthy for the investigation of metallurgical problems, as it is in accord with condition of actual operation.

**Comparative Hardness of Ores in Tube Milling.**—In the April *Journal* of the Chamber of Mines of Western Australia, Mr. W. B. Blyth contributes "a simple and accurate method for comparing the hardness of ore sands judged from a tube milling standpoint." The comparison does not extend to any other crushing machine. Stadler's method for computing the grinding efficiency is used, but the regrind factor is only an arbitrary term used for want of a better. The method is as follows:

"A sample of ore to be tested (wet crushed) is graded (I.M.M. screens) until 8 lb. of a —20 + 40 sand is obtained. A charge consisting of 8 lb. of sand, 8 lb. of flintstones, 1-in. to 2-in. diameter, and 16 lb. of water, is introduced into a 5-gal. glazed earthenware ginger-beer barrel and ground for 90 minutes at 60 r.p.m. A sample of the ground product is then taken, dried and graded with a mechanical grader, 40, 60, 100 and 150-mesh I.M.M. screens. Grading occupies 20 minutes. The value of the grading in energy units is then calculated by Stadler's method and this amount, minus the original value in energy units, represents the regrinding factor in the table."

| Screen | Feed |  |  | Product |  |  |
|---|---|---|---|---|---|---|
|  | Mean Factor, Stadler | Per Cent | Energy Units | Per Cent | Mean factor, Stadler | Energy Units |
| + 40 | 17.5 | 100 | 1750 | 16.8 | 17.5 | 294.0 |
| + 60 |  |  |  | 29.2 | 20.0 | 584.0 |
| +100 |  |  |  | 16.4 | 22.0 | 360.8 |
| +150 |  |  |  | 6.6 | 24.0 | 158.4 |
| –150 |  |  |  | 31.0 | 26.5 | 821.5 |
|  |  |  | 1750 |  |  | 2218.7 |

Total energy units, product, 2218.7; feed, 1750; difference, regrinding factor, 468.7

**Cost of Power for Air in Converting.**—In discussing this subject (Bulletin, A. I. M. E., June, 1914) Mr. Herbert Haas makes the following observations: With a good boiler 1 lb. of coal will evaporate 8 lb. of water; a good steam turbine direct-connected with a turbo-blower will consume 12 lb. of steam per effective hp-hr.; so that 1.5 lb. of coal would produce an effective hp-hr. With fuel oil, an evaporation of 14 lb. of water can be obtained from 1 lb. of oil, so that not quite 0.9 lb. of oil would be required for one effective hp-hr. With Diesel engines a hp-hr. could be produced for less than 0.5 cent, with fuel oil costing $1.50 per bbl. of 330 lb., and including 12.5 per cent interest and amortization on the capital invested. One cent per hp-hr., however, is taken as the cost of power for purposes of calculation. For converting a 40 per cent ideal matte, the author gives 101.3 hp-hr. as the commercial requirement per ton of copper for furnishing air to the converter.

## A New Porous Mineral Filter Medium

In the numerous commercial processes employed by electrochemical, chemical and metallurgical engineers in their practice there is a wide-spread need for a suitable porous medium. For processes requiring a porous diaphragm or filtering medium such materials as canvas, asbestos fiber, loose mineral substances, etc., are resorted to. These at best offer many objections, among which are the necessary and expensive renewals due to the complete destruction or rapid deterioration of the materials used and clogging of the pores, also the interruption of the operation resulting from the frequent cleaning. In many commercial processes the question of filtering thoroughly, rapidly and cheaply is a most vital one and there has been and is a wide search for a material to accomplish this work satisfactorily.

A uniformly porous septum possessing resistance to high temperatures, acids and chemical solutions and as well as showing little liability to clogging of the pores by fine particles, approaches the ideal medium for commercial filtration of gases and liquids. The development of a new porous mineral medium termed "filtros" bids fair to overcome many filtering difficulties encountered in modern industrial fields.

Filtros is composed practically of silica and is consequently inert to all acids (with the exception, of course, of hydrofluoric), the weaker alkalies most commonly requiring to be filtered in commercial practice, and neutral chemical solutions of an organic or inorganic nature. It will also withstand temperatures up to 1800° F.

The method of producing these tile was discovered by Mr. J. E. Porter, of Syracuse, N. Y. Broad patent claims on the various features of the invention have been allowed. These have been acquired by the General Filtration Company, Inc., which company also possesses a number of other patents covering the use of porous mineral septa in many industrial arts. The Harbison-Walker Refractories Company by arrangement with the General Filtration Company, Inc., manufactures the tile for the General Filtration Company, Inc.

Filtros is a white, rigid and porous ware of excellent strength. It is made in the form of standard tile 12 in. x 12 in. x $1\frac{1}{2}$ in. and where this shape can be conveniently applied there are advantages in using this size. A great variety of shapes, however, are possible for devices of special design. The pores of the standard tile are so fine as to offer great resistance to the penetration of very small particles, yet the mass is so porous as to permit the free passage of the gases or liquids to be filtered; in some instances reducing the time of filtering 50 per cent and producing a filtrate of absolute clarity. Tile of other grades of porosity than that of the standard are also produced.

The true porosities of the finer grained tile are about equal to that of the standard but the pores are much more minute, and more numerous. These are capable of retaining finer slimes but do not allow as rapid a passage of fluid as do the coarser tile.

The tests in Table I show how the true porosities compare with the air ratings. The air rating is the number of cubic feet of air per square foot of area per minute that at the given pressure pass through the tile $1\frac{1}{2}$ in. thick.

TABLE I

| Grade | Cubic feet of air at 2-in. water pressure | Porosity per cent by void |
|---|---|---|
| 5-R | 12.0 | 40.10 |
| 7-R | 8.4 | 37.44 |
| 5-1 | 6.3 | 31.56 |
| 5-2 | 4.1 | 38.24 |
| 5-3 | 2.0 | 33.27 |
| 5-4 | .50 | 39.55 |

The resistant property of filtros to high temperatures and acid fumes indicates the probable field for it in bag house practice as well as for the filtration of combustible gases without the loss of sensible heat, which, in many cases, is most desirable.

In problems of cyanidation involving aëration the exceptional uniformity in the porosity of filtros indicates its utility in this connection. The air-rating tests of Table II bear emphasis on this remarkable uniformity of the tile. These, as above, show the amount of air per square foot of area per minute that at the given pressure passes through the standard tile 1½ in. thick.

Table II

| Specimen | Cubic feet per minute per square foot at given pressure in inches: 2 inches | 4 inches |
|---|---|---|
| 1 | 12.0 | 24.3 |
| 2 | 12.0 | 23.8 |
| 3 | 11.7 | 23.0 |
| 4 | 11.9 | 24.0 |
| 5 | 12.2 | 24.5 |

Further indication of the free flow of liquids through the tile is illustrated by the tests of Table III, which give the amount of water filtered per square foot of area of the standard tile 1½ in. in thickness at the given pressure.

Table III

| Head pressure | Gallons per minute per square foot area | Temperature of water |
|---|---|---|
| 5 ft. | 1.40 | 50° F. |
| 5 " | 1.39 | " |
| 10 " | 2.15 | " |
| 10 " | 2.15 | " |
| 15 " | 2.61 | " |
| 15 " | 2.60 | 57° F. |
| 20 " | 3.27 | " |
| 25 " | 3.42 | " |

Solubility tests in which filtros tile were immersed in chemical solutions for long periods at various temperatures show the inertness of the tile to acids, weaker alkalies and chemical solutions.

The tests in Table IV representing some commercial filtrations will be of interest.

Table IV.—Commercial Filtration.

| Solution | Strength per cent | Time immersed | Temp. deg. F. | Loss | Condition unchanged |
|---|---|---|---|---|---|
| Sulphuric acid | 96 | 24 hrs. | 200 | .02 | " |
| Sulphuric acid | 96 | 8 days | " | .023 | " |
| Hydrochloric acid | 2/3 of 37 | 24 hrs. | " | .017 | " |
| Nitric acid | 1 1/3 of 70 | | | | |
| Nitric acid | 35 | 8 days | " | .016 | " |
| Hydrochloric acid | 70 | 8 days | " | .026 | " |
| Water distilled | . | 35 days | " | .000 | " |
| Sulphuric acid | 20 | 35 days | " | 110 | " |
| Hydrochloric acid | 20 | 35 days | " | 140 | " |
| Nitric acid | 20 | 35 days | " | 080 | " |
| Zinc Sulphate | Saturated | 20 days | " | 040 | " |
| Mercury Bichloride | Saturated | 20 days | " | 021 | " |
| Potassium cyanide | 2.5 | 5 days | " | .042 | " |
| Potassium cyanide | .50 | 20 days | " | 09 | " |
| Potassium cyandie | .50 | 7 days | " | 013 | " |
| Calcium hydrate | Saturated | | | | |

Fltros has been proven by test to resist also the action of organic chemicals as well.

Applications for filtros will no doubt suggest themselves to engineers for a variety of uses, such as porous diaphragms in electrolytic processes and as a filtering medium for gases and liquids in the mining, metallurgical and chemical fields. As there is at present a wide demand for a reliable and strong filtering medium for just such purposes, it will be interesting to watch the career of filtros in commercial practice.

## Dry Kilns for Timber Products

While the subject of dry kilns for timber products is of special importance to furniture manufacturers and manufacturers of wood products in general, it should also be of interest to chemical engineers in view of analogy of the process with the drying operations in many chemical processes. For this reason attention may be called to the new catalog of the American Blower Company, of Detroit, Mich., on dry kilns for timber products. (Bulletin No. 20, Series 1. 64 pages, illustrated.)

The problem of lumber drying is the removal from lumber of all moisture, of whatever form, contained in its pores. The sap is not pure water, but contains many substances in solution. All the conifers contain resin. The sap of all trees contains albumen. The ideal effect in the drying process is produced by removing not only the liquid or volatile constituents of the sap, but also those chemical compositions—albumen, starch, sugar, etc.—which by absorbing moisture, after being once dried, may set up fermentation, the initial process of decay in wood.

To produce this ideal effect the drying must commence at the heart of the board and work outwards, the moisture being removed from the surface as fast as it exudes from the pores of the wood. The catalog describes the "moist air" process which fulfills this requirement. The surface of the lumber is kept soft, the pores being opened until all the moisture within has been volatilized by the heat and carried off by the strong circulation of the air. When the moisture is removed from the pores, the surface is dried without closing the pores, resulting in lumber that is clean, soft, bright, straight and absolutely free from stains, checks, or other imperfections.

The catalog describes two general types of moist air kilns. In one the air circulation is obtained by natural means and in the other by mechanical means or forced circulation.

For natural-circulation kilns the "progressive" type is first described which operates on what is known as the "progressive" principle, the green lumber, piled on cars, entering at one end of the kiln, and being gradually moved down through the kiln as the dry lumber is removed at the other end. When green lumber first enters the kiln it is not in a condition to stand a high temperature. For this reason the floor heating coils do not extend back to the green end. Therefore, when a car of lumber is run in, it enters an atmosphere moderately high in temperature and quite moist. Under such conditions the sap within the wood is thoroughly soaked, much the same as if the lumber had been steamed. The gentle heat surrounding it starts the sap toward the surface, the drying taking place first in the center of the board.

As the car moves forward it is gradually brought into a hotter and drier atmosphere. The effect is that the moisture in the surrounding air keeps the sugars, starch, albumen, etc., near the surface, in a semi-liquid state, until all the internal moisture has been extracted. The continually increasing temperature eventually draws the moisture from the pores near the surface, and the surface itself is finally finished off in a practically dry atmosphere.

The lumber entering the kiln does not stand over any steam pipes for several hours (which would cause case hardening), but it is subjected to a mild, moist heat, preparatory to entering a more intense heat and drier atmosphere when in a proper condition to endure it without injury.

The path of the air current is longitudinal, or from end to end, not up through the middle and down the side walls as in other kilns, which results in the same temperatures and humidity from one end to the other. The cold, wet cars at one end chill the air, causing it to drop down beneath the tracks. The heat generated at the other end by the steam coils creates a partial vacuum beneath the tracks, into which the air rushes from the other end and rising up through the lumber circulates toward the wet end, this operation being continuous.

While with the "progressive kiln" the operation is continuous, it discontinues with the "apartment type" of natural circulation kilns which are especially desirable when the stock used by the manufacturer is required in comparatively small quantities, of varying thicknesses, from a diversity of woods and in varying degrees of dryness.

The second part of the catalog deals with forced-circulation kilns. The forced circulation or blower dry kiln is probably the oldest type of modern kilns. This kiln is a greater success to-day than ever before. It will turn out just as good quality, in just as short a time, as any other type of kiln on the market, and with no greater expense for operation if properly handled. This kiln is recommended especially for drying bent stock, staves, heading, shingles, hoops, lath, tub and pail stock, and it is almost universally used in these particular lines. This kiln gives best results when it is operated on the "progressive" principle; that is, the green lumber pailed on cars, enters at one end of the kiln, and is gradually moved down through the kiln toward the blower and the heater, as the dry lumber is removed from that end. When the green lumber enters the kiln it is surrounded by an atmosphere impregnated with moisture gathered from the cars ahead, over all of which the air has passed, and is subjected to a temperature from twenty to forty degrees lower than it eventually has to withstand before leaving the kiln when finally dried. The sap within the wood is thoroughly soaked, much the same as it would be if first steamed, only the effect is milder and perfectly harmless.

The heat starts to volatilize the moisture within the pores, bringing it to the surface, where it is taken up by the air and carried off. In this way the drying takes place first in the center of the board, the dampness of the surrounding atmosphere keeping the pores open, thus preventing case hardening or checking. As the car moves forward it is gradually brought into a hotter and drier atmosphere. The continually increasing temperature, with a corresponding dryness, eventually removes all the moisture, the car finally standing directly over the duct where the air rises hot and dry.

Data are given in the catalog on details of the drying equipment (heating coils, etc.), on drying kilns specialties (structural steel rail supports, trucks, traps, temperature and humidity measuring instruments), and methods of loading dry-kiln trucks.

---

**Colorado metal production** for 1913 was valued by the U. S. Geological Survey at $35,449,298. The production of zinc and gold decreased, but silver, copper and lead increased, as compared with the previous year.

The metal production is itemized as follows: Gold, $18,146,916; silver, 9,325,255 oz.; lead, 87,620,364 lb.; copper, 7,298,269 lb., and zinc, 119,346,429 lb. Cripple Creek produced 60 per cent of the total gold yield in the state. Leadville produced 79 per cent of the zinc.

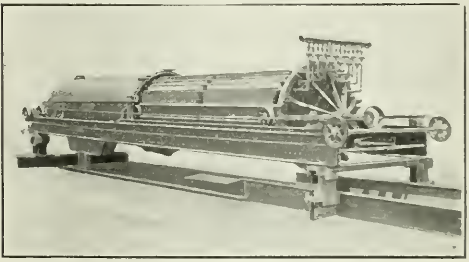
The number of the mines producing metals in 1913 was 858, of which 29 were placers, as against 856 mines, of which 33 were placers, in 1912.

## Filter Press Work in Cane Sugar Factories

Owing to the article descriptive of the Worthington filter press work in a cane sugar plant in Cuba, appearing in the July issue of this magazine, and in which certain comparisons were made with a "late type of cylinder press," we deem it only fair to publish the following article for which the Kelly Filter Press Company, of Salt Lake City, Utah, assumes full responsibility.

"The data for the so-called type of cylinder press was taken directly from page 26 of the Kelly Filter Press bulletin entitled 'Filtration Economy in All Industries,' and on account of the fact that the Kelly press is the only late type of cylinder press installed in cane sugar plants so far as can be determined, it is thought only fair to make correction in the article which appeared in the July issue of this paper.

"First and foremost, the data taken from the Kelly Filter Press bulletin was quoted incorrectly. In Table 2 of the article it was stated that the per cent of sucrose in the press cake dumped from the Kelly press was 8 per cent. *This should have been eight-tenths of 1 per cent.* The cake dumped from the Worthington press according to this article contained 6.85 per cent sucrose. In other words, 1 ton of cake dumped from the Kelly press contained 16 lb. sucrose, while 1 ton of cake dumped from the Worthington press contained 137 lb. of sucrose. The sugar saved by the Kelly press over the other type amounts to a very large saving, as a glance at the following will show.



KELLY FILTER PRESS IN SUGAR PLANT

"Assuming a cane sugar factory grinding 1000 tons of cane per twenty-four hours, and that in such a factory the weight of filter cake dumped approximates 1.5 per cent on the weight of cane crushed, there would be 15 tons of filter press cake dumped per twenty-four hours from plate and frame presses.

"In two separate tables in the previous article it was stated that the cake dumped from the Worthington press contained 6.85 per cent sucrose. This would be, therefore, 1.03 tons, or 2060 lb. of sucrose per twenty-four hours. An equivalent amount of cake dumped from the Kelly press contains only 0.8 per cent sucrose, which would equal approximately 0.2 ton, or 400 lb., of sucrose per twenty-four hours. The difference is 1660 lb. of sucrose in favor of the Kelly. Assuming that 92 per cent of this can be recovered as 96 deg. sugar, then 1527 lb. of sucrose is saved every twenty-four hours by Kelly filter-press methods. It will cost, say, ¼ cent per pound to make this into sugar. If sugar is worth 2¼ cents per pound, then we can figure the actual value of sugar per pound at this station at 2 cents. *This means a sucrose saving per day of* $30.54, which on a 200-day campaign would equal $6,104.

"It is in savings of this nature and magnitude by which the Kelly press has proven its worth as an efficient filter.

### Length of Cycle

"In the previous article in Table 2, it is stated that the average of the Worthington cycle is forty-five minutes and that of the Kelly press is 160 minutes. This gives an incorrect impression due to the fact that a period of wash was used in the Kelly press cycle, and evidently no wash was used in the cycle of the Worthington press.

"The cake dumped from the Worthington press per cycle is given at 179 lb., containing 58.42 per cent and 6.85 per cent sugar. The remaining portion of the cake would therefore represent 34.73 per cent of the weight which would be the dry insolubles. The amount of solids would therefore be 62 lb. per cycle. According to our data sheet, there are approximately 279 lb. of dry insolubles per cycle dumped from the Kelly press. The filter area of the Worthington press is given as 300 sq. ft., while that in the Kelly press is 420 sq. ft. This shows a capacity of 0.207 lb. of cake per square foot of filter area per cycle in the Worthington press, as against 0.66 lb. per square foot of filter area per cycle in the Kelly press.

"It seems to be a predominant opinion among cane sugar men that it is absolutely essential to have a washing machine in connection with the filter press department for washing the filter bags. We cannot emphasize too strongly the fact that we do not require a washing machine in connection with the Kelly press because the cloths are washed thoroughly inside of the press.

"The claim is made the same set of bags was used continuously until worn out. They are not removed from the press for washing. The permeability of the cloths is restored each cycle, thereby constantly maintaining high efficiency in the ratio of filtration of the cachaza.

"Another feature of the Kelly operation which we wish to emphasize is the fact that the sugar is washed out of the filter press cake directly in the press, and that such wash is practically perfect, the sugar being virtually pushed out of the cake in place; or, in other words, displaced directly with water. This means a minimum dilution of the sugar juices. It has been proven that this dilution is negligible as compared to that resulting from the addition of water to the cachaza before filter pressing, or the dilution accompanying the disintegration of filter cake with water followed by a secondary filtering operation, as sometimes practiced in connection with the plate and frame presses. The latter, we assume, is the method of obviating sucrose losses in the Worthington press.

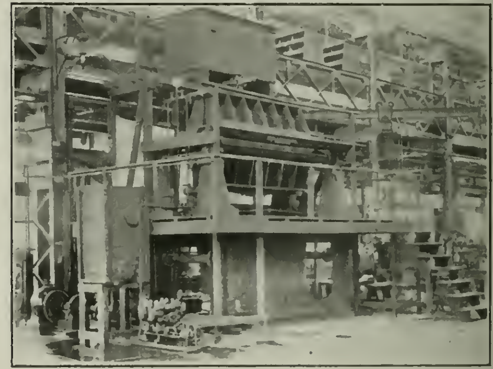
"We would be very glad to compare the brightness of the juices after filtration by the Kelly press; life of filter bags; labor required; the heat conserved; the leakage, breakage and maintenance costs and repairs with that obtained by any other filter apparatus on the market.

"The data above submitted for the operation of the Kelly press have been taken from tests made under the supervision of the chemist of the Adeline sugar factory where eight Kelly presses are installed. Those readers desiring more complete detail on the above data, may be referred to insert at page 26, of the Kelly Press Company's bulletin, which will be furnished upon request by that company."

**Materials of engineering construction** will be one of the subjects considered at the International Engineering Congress, 1915. Among the topics that will be covered will be timber preservation, clay products, concrete, special steel, copper and alloys, aluminum, and the testing of materials. Full information can be had from the Congress, Foxcroft Bldg., San Francisco.

## Filter Press Laboratory

In a recent issue we described the Worthington press as installed in a Cuban sugar central. It is to be noted that this invention and improvement is one that will materially aid this particular industry. The press is, however, suitable for many other purposes such as dewatering of slimes. Methods developed in this press bring out the possibility of handling colloids without the introduction of any unnecessary amount of sand, inasmuch as it does not force through the cake or the filtering medium, obviating closing of same. The use of this press in handling wool grease or sludge, as well as sewage and tankage, has been fully demonstrated and accomplished. Its importance in handling clay products rapidly and continuously has been proven. It is a self-contained construction with easy accessibility and gives many advantages, such as quick and efficient closing and opening for charging and discharging, quick dropping of cake by gravity, manual labor cut down to the smallest, and power consumption hardly any. Such simplification and easy manipulation, saving in filter cloth and greater recovery in either clear liquors or clean press cakes, gives an improvement that means reduction in cost of operation.



WORTHINGTON FILTER PRESS LABORATORY

The illustration shows the laboratory of Henry R. Worthington, Harrison, N. J., where a 6-ft. x 9-ft. press is in operation for experimental purposes, all completely fitted up with agitator tank, filling pipes, supply pump for material to be filtered and small pressure pump producing final squeeze. The press shown has automatic closing features operated by water pressure and self-dumping bag arrangement for dropping cake in a belt conveyor. There is maintained a complete chemical and experimental laboratory, where all filtration tests are made of material sent by prospective customers. They have a corps of efficient and practical filtration experts and engineers, who install and start these presses to get the best results.

**Brass-Furnace Practice** is the title of **Bulletin 73**, by H. M. Gillett, recently issued by the U. S. Bureau of Mines. It contains a report into the losses sustained in melting nonferrous alloys, which amount to about 5 per cent of the original metal. It is shown that from 90 per cent to 95 per cent of the heat units in fuel used in melting do no useful work. The financial saving to be effected by improved practice in melting, due to reduced loss of metal, increased efficiency of fuel and crucible life, is estimated to be about two million dollars.

## Hydraulic Reducing Valve

The adjoining illustrations show a new type of hydraulic reducing valve which the Auld Company, 1247 North 12th Street, Philadelphia, is just putting on the market. The illustration shows a 4-in. valve for an inlet pressure of 800 lb. and an outlet pressure of 500 lb. The construction of the valve is simple and all parts are strong enough to insure that it will give continuous and reliable service. The outlet pressure does not vary, though the volumes of water being passed through the valve may vary. The operation of the valve is as follows:

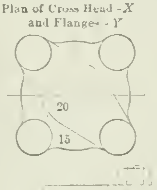
The initial pressure enters by the branch marked "inlet" and acts between the main valve 7 and the piston 4. The piston is of greater area than the valve 7 and therefore the main valve is held tightly shut on its seat 8. To prevent water from passing from the top to the bottom side of the main piston 4 a cup leather 6 is fitted.

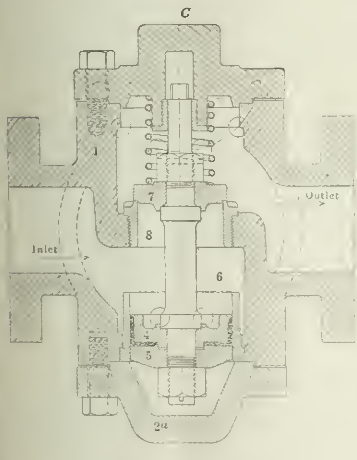
The initial pressure passes from the high-pressure side into the port $B^1$ which communicates with the space at the top side of the regulating valve 13. This regulating valve is held open by action of the spring 23 and the high pressure is allowed to pass through the valve 13 and down the pipe 22 into the chamber under the piston plate 5.

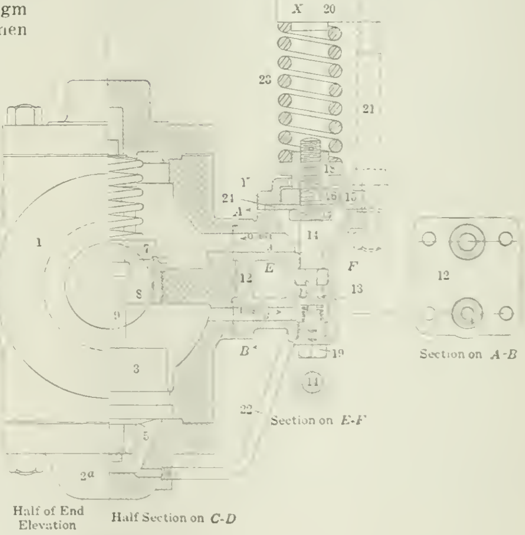
With high pressure acting on both sides of the piston 4, the valve 7 is forced open, due to the area of piston 4 being greater than the valve 7, and pressure flows into the outlet or low-pressure side. The low-pressure side of the main valve body 1 is connected to the diaphragm chamber of the regulating valve by port $A^1$ and when the pressure under the diaphragm acting on the area of the piston 16 exceeds the load which the spring 23 is set at it forces up piston 16 and valve 13 stopping the flow of water to the underside of the piston 4 (i.e., chamber under piston plate *S*) and allows the main valve 7 to come to its seat and stops the flow of pressure from the inlet side.

There is a constant leakage from the underside of piston 4 to the low-pressure side through the slots cut in the body of the regulating valve (shown at section on *EF*) and when the regulating valve 13 closes, the surplus water under the piston 4 is forced out through the pipe 22, through these slots into the diaphragm chamber and through the port $A^1$ into the low-pressure side of the main valve body. This action is repeated so long as the pressure on the outlet side tends to vary.

A slight variation of the outlet pressure is sufficient to operate the reducing valves and any fluctuations which take place are thereby rendered negligible.







HYDRAULIC REDUCING VALVE

## Personal

Dr. **Lucien I. Blake**, well known for his inventions in the field of electrostatic ore separation, is delivering a series of lectures on Cosmic Physics at the University of California. He will spend some time in Denver after concluding his engagement about August 1.

Dr. **Leo H. Baekeland**, of Yonkers, N. Y., started on July 11th on a trip around the world. He is now en route to Japan and Korea.

Mr. **Albert Burch** will have general management of the Aurora Consolidated mine and mill which was recently acquired by the Wingfield interests. He will retain also general management of the Goldfield Consolidated. Mr. **K. M. Simpson** has been made assistant general manager of the latter company.

Mr. **J. M. Callow**, of the General Engineering Co., Salt Lake City, Utah, is supervising the installation of the 200-ton experimental flotation plant for the Inspiration Consolidated Copper Co., Miami, Ariz.

Mr. **Fred Close**, metallurgical engineer of London, has returned from a professional trip to Alaska.

Mr. **J. V. N. Dorr** received the honorary degree of Mining Engineer at the recent commencement of Rutgers College, in recognition of his work in the metallurgy of gold and silver.

Mr. **R. C. Gemmell**, general manager of the Utah Copper Co., was chairman of the organization committee having in charge the establishment of a branch of the American Institute of Mining Engineers in Salt Lake City. The organization meeting was held August 13.

Mr. **W. G. Haldane**, acting president of the Colorado School of Mines, was granted the degree of Doctor of Science at the commencement exercises of Denver University.

Mr. **H. W. Hardinge** is on a business trip through Canada, Alaska and the western United States.

Mr. **D. C. Jackling**, managing director of the Utah and other copper companies, has returned from his Alaskan trip. He expects to go East for conference with his associates and will then return to Alaska.

Mr. **J. W. Jeffrey** was recently elected second vice-president of the Jeffrey Manufacturing Co., Columbus, O.

Mr. **C. D. Kaeding**, formerly assistant general manager for the Goldfield Consolidated Mines Co., Nevada, has been appointed vice-president and general manager for the Dome Mines Co., Ltd., at South Porcupine, Ontario.

Mr. **F. A. Kaufmann** has resigned his position with the Tottenville Copper Company and is now connected with the Roessler & Hasslacher Chemical Company at Perth Amboy, N. J., as chemical engineer.

Mr. **Guy M. Kerr**, formerly superintendent of the Arkansas Valley plant of the A. S. & R. Co., Leadville, Col., has been transferred to an executive position at the Garfield smelter, near Salt Lake City. He is succeeded at Leadville by Mr. **J. F. Austin**, formerly superintendent of the same company's plant at Monterey, Mexico.

Mr. **William D. Leonard** has been appointed superintendent of the Garfield Smelting Works, Garfield, Utah.

Mr. **Bernard MacDonald** has removed his office from Pasadena to 533 I. W. Hellman Bldg., Los Angeles, Cal.

Dr. **Harold Pender**, professor of electrical engineering at the Massachusetts Institute of Technology and director of the research division of the department of electrical engineering, has been invited to become professor-in-charge of the department of electrical engineering at the University of Pennsylvania, and has accepted this invitation, which will become effective next fall. Heretofore the departments of mechanical and electrical engineering at the University of Pennsylvania have been under the joint direction of the Whitney professor of dynamical engineering. From the beginning of next year the department of electrical engineering will be on an independent and coordinate footing with the departments of civil and mechanical engineering.

Dr. **Edward D. Peters** was given the honorary degree of Doctor in Engineering by the Royal School of Mines, Freiberg, Saxony.

Mr. **William C. Post** has resigned his position as metallurgical engineer with the Illinois Steel Co., and will take a similar position with the Jeffrey Manufacturing Co., Columbus, O.

Dr. **Rossiter W. Raymond** delivered the commencement address at the Colorado School of Mines. While in Denver he was the guest of honor at a dinner tendered by the local scientific and mining men.

Mr. **P. A. Robbins**, general manager for the Hollinger Gold Mines Co., Timmins, Ontario, has returned from a trip abroad and resumed his duties.

Prof. **Robert H. Richards** has been making a tour of the Western metallurgical centers gathering data on ore dressing. The itinerary includes Lake Superior, Montana, Idaho, California, Nevada and Utah.

Mr. **Robert C. Sticht**, general manager of the Mt. Lyell Mining & Railway Co., Tasmania, is on an extended vacation which will take him to Germany. On his trip through the United States he has visited the scenes of his former activities in smelting in Montana and Colorado. While in Denver, Mr. Sticht was the guest at a dinner given by the Colorado Scientific Society, of which he has been a member for over 30 years.

Mr. **L. C. Turnock** has resigned his position with the Pennsylvania State College as head of the Department of Electrochemical Engineering, which he has held for the past three years, and has accepted a position with the Edison Storage Battery Company in Orange, N. J.

## Obituary

We have been advised of the accidental death on June 29 of **Arthur Austin**, chief chemist for the International Smelting & Refining Co., at Tooele, Utah. He was engaged in testing work and had been experimenting with oil burners. A steel oil-container under high pressure exploded, covering him with oil which immediately caught fire. He was so severely burned that he died a few hours later. He leaves a widow and young child. He was a son of L. S. Austin, a graduate of the Colorado School of Mines, '05, and had been in the employ of the Anaconda Copper Mining Co. practically since his graduation. He was transferred to the Tooele works several years ago. In his work with these companies he had given excellent satisfaction, and showed promise of developing into a competent metallurgist.

**Benjamin F. Thomas**, of Chattanooga, Tenn., died in Atlantic City, N. J., on June 25, at the age of fifty-two years. He was ill only a few months, having suffered a stroke of paralysis in January. He was one of the founders of the Coca-Cola Company and president of the Coca-Cola Bottling Company. Mr. Thomas was interested in many departments of technical chemistry and will be remembered by our readers as a constant and jovial attendant at the meetings of the American Electrochemical Society.

## Notes

**A patented substitute for platinum** to be used for electrical contacts consists of an alloy of 45 per cent platinum, 15 per cent gold, 25 per cent silver and 15 per cent copper.

**Stratton's Independence, Ltd.**, Cripple Creek, Col., milled 11,800 tons of low-grade mine and dump ore in the month of May, 1914, yielded a net working profit to the company from both mine and mill departments of $10,150.

**Stamp duty on the Rand** is steadily increasing. In 1908 it was 6.27 tons per stamp in 24 hours. In 1909 it was 6.79; in 1910, 7.19; in 1911, 7.88; in 1912, 8.39; and in 1913, 8.82. It is anticipated that the duty for 1914 will average 9 tons or over.

**Transvaal Gold Production.**—The number of companies reporting to the Transvaal Chamber of Mines in April, 1914, was 60. The total quantity of ore milled during that period was 2,130,545 tons. There were 9695 stamps in operation, with an average duty of 8.85 tons per stamp in 24 hours. Tube mills in commission numbered 290. The yield for the month was 683,877 fine ounces of gold. Compared with the report of a year ago the current report shows 350 fewer stamps dropping, but 5 more tube mills in commission. The current yield is less than that of April, 1913, by 101,097 ounces gold. The yield per ton milled is about the same as a year ago.

**Steel Chain Belt.**—The Chain Belt Company, of Milwaukee, Wis., have issued their illustrated catalog No. 59 on Chabelco steel chain belt. This is an all-steel, case-hardened-bearing roller chain belt designed to meet the most difficult conditions. The side bars are punched from mild-steel bar stock. The rollers for transmission purposes are made of the best grade of cold-rolled steel shafting, machined out of the solid on automatic turret lathes. The rollers for elevating and conveying purposes are made of cold-rolled steel, cast steel or grey iron. The bushings are stamped out of cold-rolled pickled steel. The pins are made of forged steel and milled flat on ends to fit oblong hole in side bar to prevent turning. Every pin and bushing is case-hardened and heat-treated. Chabelco steel chain belt can be used by practically every industry for elevators and conveying and transmission purposes and has been introduced with particular success in pulp and paper mills, power houses, canning plants, cement mills, fertilizer plants, packing houses, ice plants, oil wells, sand and gravel plants, glass plants and potteries. Chabelco steel chain belt is also used on the same company's pivoted bucket systems of both overlapping and contact-lip type; the capacities of these systems range from 20 tons per hour up. A special study of methods for handling coal and ashes has also been made by the Chain Belt Company. The catalog is well illustrated and gives details of types, sizes and dimensions.

**Secondary metals recovered from waste and scrap**, exclusive of gold, silver, platinum and iron, in the United States in 1913, had a gross value of $72,845,000. After remelting and refining these secondary metals sell at only slightly lower prices than new metals. For purposes requiring metal of exceptional purity it is necessary to use virgin metal, but otherwise the secondary metals can be used in whole or in part. The use of magnetic separation in the recovery of secondary metals is on the increase. Following is a tabulation of secondary metal production, prepared by the U. S. Geological Survey:

*Production of Secondary Metals in the United States in 1912 and 1913*

| | 1912 | | 1913 | |
|---|---|---|---|---|
| Metal. | Short tons. | Value. | Short tons. | Value. |
| Secondary copper, including that in alloys other than brass .... | 66,441 | $21,593,325 | 66,980 | $20,536,068 |
| Remelted brass ....... | 101,523 | 27,279,516 | 99,315 | 24,651,969 |
| Secondary lead ....... | 30,266 | 6,045,120 | 33,104 | 6,409,392 |
| Recovered lead in alloys | 36,902 | | 39,730 | |
| Secondary spelter ..... | 32,251 | 7,750,491 | 50,005 | 6,019,776 |
| Recovered zinc in alloys other than brass .... | 3,912 | | 3,743 | |
| Secondary tin ........ | 8,333 | 14,301,368 | 6,415 | 12,567,379 |
| Recovered tin in alloys | 7,068 | | 7,763 | |
| Secondary antimony ... | 13 | 426,020 | 45 | 460,932 |
| Recovered antimony in alloys .............. | 2,493 | | 2,660 | |
| Secondary aluminum .. | ..... | ......... | 2,198 | 2,199,180 |
| Recovered aluminum in alloys .............. | ..... | ......... | 2,456 | |
| Total value ....... | | $77,395,843 | | $72,844,996 |

**The production of primary refined lead** in the United States in 1913 amounted 462,460 short tons, being a decrease of 18,434 tons, or 3.8 per cent., compared with the output of 1912. The production of secondary lead was 72,834 tons.

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

*Electroplating* (Continued)

453,355, June 2, 1891, Alexander Elliot Haswell and Arthur George Haswell, of Vienna, Austria-Hungary.

Relates to coating metals, such as iron or steel, with an anti-corrosive deposit of binoxide of lead or of a mixture of binoxide of lead with binoxide of manganese by means of a galvanic current. The bath contains one liter of water, eight to eighty grams of nitrate of lead and twenty to fifty grams of nitrate of ammonia. The article to be coated is connected to the positive pole of a source of current and immersed in said bath. In practice, good results have been obtained with a current strength of one-half ampere to one ampere per square decimeter surface of the article to be coated, and a tension of two volts to two and one-half volts. The temperature of the bath may vary from 64 deg. to 75 deg. Fahr. A suitable deposit is obtained in about ten minutes. To the above bath may be added about half a gram of nitrate of protoxide of manganese; this will give a deposit of binoxide of manganese along with the binoxide of lead.

476,639, June 7, 1892, Alexander Elliot Haswell and Arthur George Haswell, of Vienna, Austria-Hungary.

Relates to forming deposits of oxides on metals by electrolysis, and is an improvement on their earlier patent No. 453,355, dated June 2, 1891.

For preparing the improved bath, eighty grams of nitrate of lead are dissolved in five hundred grams of water and this solution poured into six hundred and thirty-five grams of caustic soda solution, having a specific gravity of 1.27, equal to 31 deg. B., and containing one hundred and fifty-eight grams caustic soda. After mixing ten grams of finely powdered carbonate of manganese are added and the bath well stirred during electrolysis. The article to be coated is connected to the positive pole and immersed in the bath. In practice, good results have been obtained with a current of one-half to one ampere per square decimeter of surface to be coated, and a tension of from two to two and one-half volts. The temperature of the bath may vary from 64 deg. to 75 deg. F. A deposit of suitable thickness may be obtained in about ten minutes.

509,124, November 21, 1893, Hannibal Goodwin, of Newark, N. J.

Relates to electro-etching of plates, etc., and describes several well-known methods of producing a design, etc., upon a plate by photographic means. The metal to be dissolved, or etched, is finally exposed, the plate suitably waxed and connected as an anode, and etched in any suitable electrolyte. A plate to be etched and a cathode are suspended in a cell, and connected in series to another plate and cathode in another cell, a number of such plates so connected are electrolyzed by a dynamo current, instead of electrolyzing plates separately by a battery current.

514,896, February 20, 1894, Craig Ritchie Arnold, of Sharon Hill, Pa.

Relates to processes of coating metals with oxides, the article to be coated being connected as anode in a solution of the metal to be deposited as oxide. For depositing peroxide of lead, the anode is immersed in a solution made as follows: to prepare twenty-two gallons, dissolve twenty-two pounds of nitrate of lead in seven gallons of hot water; this solution is poured into eleven gallons of caustic soda of 1.20 sp. gr., after having been warmed to 70 deg. C. After about thirty minutes, and when cool, sufficient water is added to bring it to the required volume. During plating, finely divided litharge is added to the solution, and thoroughly agitated. The cathode is placed in a porous cup containing a concentrated solution of caustic soda, either alone, or in combination with bichromate of soda; caustic soda is preferred, although bichromate of soda may be used as the equivalent.

517,275, March 27, 1894, Hannibal Goodwin, of Newark, N. J.

Relates to the decoration of gold or silver by electro-etching and oxidizing or depositing. A suitable design is applied to a gold or silver surface by any of the usual means; the gold or silver is then connected as an anode and suspended in a solution containing iodine, preferably potassium iodide containing free iodine. The electrolysis produces a quick and perfect etching of the unprotected parts of the plate without disintegrating the resisting matter applied for insulation. Since it is very difficult to apply a different color to gold by oxidation, patentee deposits silver upon the etched surface of the gold, and then oxidizes or platinizes the silver; or any other contrasting metal may be substituted for the silver.

526,114, September 18, 1894, Emile Placet and Joseph Bonnet, of Paris, France.

Relates to the electrodeposition of chromium, from aqueous and fused baths; also to the deposition of chromium alloys. For the aqueous solutions, chromic acid or a chromic salt is dissolved in water, to which may be added an acid, and also one or several of a plurality of substances which vary the tint of the deposited metal. For alloys, a salt of the metal to be added is dissolved in the electrolyte. The patent should be consulted for details.

534,259, February 19, 1895, Pompeo Garuti, of Florence, Italy.

Relates to an apparatus for the electrolysis of water, and preferably consists of a lead-lined tank in which is placed an inverted box-like compartment divided into a plurality of separate narrow cells by diaphragms. Anodes and cathodes are placed in alternate cells, the tops of the latter having openings or vents to permit the oxygen or hydrogen to pass into collecting tubes. The electrolyte is preferably pure water containing twelve per cent. of its weight of commercial sulfuric acid of 60 deg. With an acid electrolyte, it is preferred to make the entire apparatus of lead. Instead of acid, a 15 per cent solution of caustic soda or potash may be used, in which case the apparatus may be made of cast or wrought iron, or steel.

534,895, February 26, 1895, William H. Legate, of Hartford, Conn.

Relates to a method of and apparatus for marking and ornamenting tableware, such as knives, etc., and other articles. The article to be marked is coated with a suitable varnish; a metal stamp bearing the design to be imprinted is moistened with strong potash solution and pressed against the varnished surface. The potash dissolves the varnish, exposing the metal in the outline of the design; the article is now washed with water, and then in solution of ammonium chloride is applied to the exposed metal. The knife or other article is now connected as an anode, and the metal stamp as cathode; the electric current etching the article and fixing the mark or design. The article is then washed in potash to remove the varnish, and may be further treated as desired. The apparatus consists of a frame to hold a pluarility of knives, etc., and a plurality of metal stamps, in fixed relation to each other.

*(To be continued)*

## Book Reviews.

**Organometallic Compounds of Zinc and Magnesium. By Henry Wren, Ph.D.,** 12mo. (12 x 15.5 cm.), 100 pages; price $0.75 net. New York: D. Van Nostrand Company.

A monograph which will give the organic chemist a good résumé of the Grignard reactions with magnesium salts and the corresponding zinc salt reactions. It is particularly concerned with the use of these reactions as intermediaries in isolating difficult organic compounds. It has practically no interest for the metallurgist or electrochemist, since the properties of these organic metallic compounds are scarcely mentioned, and their possible uses in and of themselves ignored. The illuminating and suggestive book on organic-metallic compounds has yet to be written.

* * *

**The American Fertilizer Hand Book.**—Seventh Annual Edition: 1914. 456 pages. Price, $1.00. Philadelphia, Pa.: Ware Bros. Company.

The 1914 edition of the well known and useful annual Fertilizer Hand Book contains the usual statistical matter, brought up to date, on the fertilizer trade, the cotton seed oil industry, packing and rendering plants, etc., together with a number of specially prepared annual reviews. Among these we note the following: "The Sulphuric Acid Industry," by Andrew M. Fairlie; "Available Phosphates by Furnace Treatment," by James H. Payne; "Available Nitrogen in Compounds," by E. P. Verner; "Present State of the Cyanamid Industry," by E. J. Pranke; "The World-Wide Search for Potash," by Harry Wilson; "Mining of Florida Pebble Phosphate Rock," by Thomas M. Peters; "The Products of Cottonseed," by Thos. C. Law; "The Use of Packing-House By-Products," by J. B. Sardy.

* * *

**The Rolling Mill Industry. By F. H. Kindl, Engineer.** Octavo, 76 pages, 27 illus. Price, cloth binding, $2; flexible leather, $3. Cleveland, Ohio: The Penton Publishing Company.

According to the title page, this is "a condensed general description of iron and steel rolling mills and their products," and according to page 1, the author has in view to furnish those engaged in the iron and steel business with "a comprehensive knowledge pertaining to this important branch of the iron and steel industry."

The book fails absolutely in its avowed purposes. It is written as if for children under ten years old. The German word "*kindlich*" describes it exactly—with apologies to the author for borrowing his name to describe his book.

* * *

**Electric Furnaces for Making Iron and Steel. By Dorsey A. Lyon and Robert M. Keeney.** 142 pages, 36 illustrations. Bulletin 67 of Bureau of Mines, Washington, D. C.

This pamphlet of the Bureau of Mines is an excellent and timely summary of the history of electric iron ore reduction and electric steel refining and of the present status of the art. The first chapter, by Dorsey A. Lyon (p. 7 to 57), deals with the electric furnace in pig iron manufacture; the second chapter, by Robert M. Keeney (p. 58 to 137), with the electric furnace in steel manufacture. All furnace designs which have achieved any importance are concisely described and illustrated, together with a few typical installations. Some figures of cost are added. This is a decidedly useful piece of work of the Bureau of Mines.

## The European War

War is hell. Our knowledge of what is happening on the other side of the Atlantic comes to us through a rapid sequence of extra-editions of newspapers and while this highly excitable moving picture show of glaring headlines, more or less contradictory, passes before our eyes, we see only one thing clearly—that a gigantic calamity has come over Europe—and we pause quietly to ask why this whole terrible thing is going on.

Have men whom we have known intimately for years and have admired for their peaceful achievements in arts and sciences, suddenly gone crazy? Have practically all Europeans suddenly gone crazy? If we want to avoid this conclusion, nothing is left but the inference that the psychology of nations is different from the psychology of individuals.

Nor is this inference unwarranted. We know that an individual acts differently in a crowd than when left to himself. We know that we may be impressed quite differently by a silver-tongued orator if we hear him in the midst of a sympathetic crowd than when we read his sophisms in the quiet of our home. And when in the past the Devil wanted to try a particularly interesting human reaction, he created a boom in a mining camp. Mark Twain has sketched vividly how the actions of otherwise perfectly sensible and normal men become abnormal in a mining boom. The fact is that when crowd psychology of which national psychology is a variety, gets the best of individual psychology, the "free will" of the individual is gone; there remains not much more of it than the "mean free path" of an atom. Crowds and nations then act under the blind forces of Nature. In the gigantic human reaction which the European war represents, the most celebrated individualities do not seem to have much more freedom of will than the "free" ions of the dissociation theory. And this is the most terrible thing in the situation, because if it is so, it means that the thing must go on to its most brutally complete conclusion.

There are clear-cut reversible chemical reactions. The European war is nothing of the kind. It is irreversible in all its phases and it is a horrid melee of half a dozen or more human reactions so that we cannot say which are primary or secondary—the hatred of race against race or commercial rivalry and envy or a revenge idea or an excess of militaristic autocracy or what else. We only know with absolute certainty that because it is an irreversible reaction its outcome is determined by the second principle of thermodynamics. Whatever may be the detailed result of the war for this or that country or nation, in the whole there must be a frightful increase of entropy. That is, European civilization as a whole must be reduced from a place in the sun to a temperature much nearer absolute zero.

* * *

The more carefully these reactions are restricted to Europe as an isolated system, the better for the rest of the world. President Wilson has been happy in defining the function of this country. There is no cause for alarm, but an opportunity for this nation to reap great permanent glory provided nobody loses his head. Our opportunity does not lie in war but in a control which will fit us, above of all nations of the world, to act for peace when the time comes.

How greatly this country is affected by the European war, is clearly evident in the situation of the metallurgical industries. We may simply look at the two extremes, copper and zinc, the former being hit hard, the latter being benefited by the war.

Half the copper output of this country has been exported in the past. Accordingly the copper production of this country has been cut in half by mines and refineries. While this was undoubtedly the wisest thing to do it means an irrecoverable loss of interest on half the plant investment.

On the other hand, zinc has been put in an enviable position by the fact that the zinc smelting centers of continental Europe are in the zone of war operations. Liege has been for zinc what Pittsburgh is for iron. Our opportunity to export zinc and galvanized iron products to South America is evident. The opportunity of electric zinc smelting is also clear. Our friend, Woolsey McA. Johnson, the American pioneer in this field, has been a brilliant writer on the subject and a clever experimenter in the past. The psychological moment has come for him and his people to deliver the goods in their projected plant at Keokuk.

As to the effects of the European war on the chemical industries of this country, the President's safe and sane advice—to keep a level head on our shoulders—is also the keynote of our interview with Dr. William H. Nichols published elsewhere in this issue.

If American chemists follow this advice, there is a great mission ahead of them. It would seem that the primary endeavor of the American chemical industry should not be so much a search for new markets (though this side of the situation should not be neglected), but a vigorous effort to assist general industry in this country to accommodate itself to the changed conditions. The substitution of glucose for sugar for part of its uses and other instances mentioned by Dr. Nichols show the possibilities ahead of the American chemists.

What enormous adaptations will have to be made in the way of using other materials or means to replace those no longer at the disposal of home industries, it is even yet very difficult to discern. But unless the chemical industry throws its whole efforts into the co-operation, it will find in the already threatening restriction of general industry its own bitter retribution.

On the other hand, the industries consuming chemicals must also keep a cool head. Already there has been too much buying; and even in products in which there is no reason to anticipate the slightest shortage, ignorant and thoughtless attempts to lay in unnecessarily large stocks have resulted in absurd increases of prices.

In other cases it will be necessary to recognize and provide for the total impossibility to obtain certain products on which our industries have come to rely, and it becomes essential to search for substitutes. Naturally those industries which have already provided themselves with chemical staffs and research facilities will be the most successful in finding quickly substitutes or developing means of doing without altogether.

It is, however, unfortunately to be feared that a very large number of lines of manufacture will probably have to depend upon the chemical industry for advice and technical assistance. Though we are confident that this assistance and advice will be cheerfully and even enthusiastically given, it surely will in many cases look like heaping coals of fire on heads which have too often treated the chemical industries of this country with scant consideration.

## As Seen After Twenty Years

A prominent metallurgical engineer visiting this country after an absence of almost twenty years said to us recently that one of the great changes he observed in his travel through the United States was the frankness of metallurgists in discussing their technical problems, and their generosity in making public the data on experimental and routine work. The former reticence, noticeable twenty years ago, has almost disappeared. The empirical "secrets of the trade" are no longer valuable, having been displaced largely by exact technical knowledge and skill. As we have advanced beyond the "muscular metallurgy" of the early days of smelting, so have we broadened our conception of self-interest to embrace the welfare and progress of our neighbor.

Another change observed by our visitor, in marked contrast to conditions two decades ago, is the great increase in the number of trained workers in our metallurgical works, and the moral and financial support given to experimental and research work by operating concerns. To-day technical graduates are found in many positions formerly held by untrained men. The foreman or boss of twenty years ago, whose chief claim to ability and distinction in many cases was physical prowess, is now supplanted by the "educated cuss" who, if physically less awe-inspiring and commanding, is mentally abler to relieve his superiors of attention to technical details. And so on down the line.

A third observation of favorable comparison between present and former conditions in the metallurgical industry is the growth in size and influence of technical societies, and the service rendered to the profession by engineering magazines. Owing to world-wide facilities for communication and dissemination of knowledge, this is a feature of our progress easily appreciated by our visitor without making a trip to scenes of former activity. Returning after many years spent in a foreign land, he finds that through such agencies, particularly those of the United States, he has been able to overcome the possible handicap of isolation.

It would be difficult indeed wholly to separate cause from effect in this wonderful change and improvement. Schools, societies and magazines have stimulated improvement and encouraged progress; at the same time they have been beneficiaries of the conditions they sought to create. Encouraged by the prospect of employment in a dignified and honorable profession, young men have crowded our schools of mining and metallurgy, later joining the great body of engineers who simultaneously support and receive inspiration from technical societies and magazines. The proud eminence which American metallurgy holds to-day is broadly the result of action and reaction among these great co-operating influences.

## Scrap and Finished Steel Production

At intervals since early in the year statistics of production in the various branches of the steel industry in 1913 have been returned by the Bureau of Statistics of the American Iron and Steel Institute and have been discussed in these columns. In the past month the last of the 1913 statistics have appeared, detailing the production of bars, skelp, nail plate, etc., and permitting a statement of the total rolled steel output for the year. The presentation is of interest by reason of the comparison that can be made with the total production of steel ingotts, showing the loss in manufacture and thus indicating approximately the amount of scrap resulting. The statistics of rolled steel are complete, covering the weight of material after the last hot rolling operation (with shearing), and thus taking cognizance of rods rather than of rod billets or drawn wire, black plates rather than either tin plate or sheet bars, skelp rather than welded pipe, and so on. Rolled forging billets and exported blooms, billets, sheet bars, etc., are included, as otherwise the material involved would be lost to the statistics.

The statistics of the production of steel ingots (excluding castings) and of rolled steel, together with the difference and the percentage the difference constituted of the ingot tonnage, are shown in the table below, for the past four years, in gross tons:

| | Steel ingots. | Rolled steel. | Difference. | Per cent. |
|---|---|---|---|---|
| 1910.... | 25,154,087 | 20,939,353 | 4,214,734 | 16.4 |
| 1911.... | 23,029,479 | 17,812,823 | 5,216,656 | 22.6 |
| 1912.... | 30,284,682 | 23,019,259 | 7,265,423 | 24.0 |
| 1913.... | 30,280,130 | 23,112,986 | 7,167,144 | 23.7 |

The sharp increase in the difference between ingot and rolled steel tonnage is remarkable and is probably attributable to a variety of causes, the proportionately greater increase in the production of steel involving many rollings, sheets, and black plates, for instance, as compared with rails, deeper cropping for the purpose of producing sound steel, and perhaps a definite desire upon the part of the steel makers to produce scrap for the open-hearth.

The experience of the past two years may be taken as representative of present-day practice, a loss of 24 per cent in weight from the ingot to the rolled steel. Part of this loss is scale, but by far the greater part is scrap. Very nearly all the scrap passes at once to the open-hearth furnace, to be used again in the production of steel ingots. A small part, doubtless, goes to steel furnaces for the production of castings, but as the production of open-hearth castings was only 910,216 tons in 1913 this item is relatively unimportant. On the other hand, there is new scrap produced in the fabrication of rolled steel, as in pipe mills, structural shops, etc. Estimating as closely as possible, but still roughly, the various additions and deductions, one may conclude that in 1913 about 6,500,000 tons of new steel scrap, produced in steel rolling mills, pipe mills, fabricating shops, etc., found its way into acid and basic open-hearth steel furnaces for the production of steel ingots.

We have statistics of the production of basic pig iron, practically all of this material passing to the basic open-hearth steel furnace, but no corresponding statistics of the production of pig iron for the acid open-hearth furnace, hence no comparison can be made of scrap and pig iron for the open-hearth industry as a whole. On the assumption that proportions were the same, an assumption that can lead to no serious error on account of the relatively small tonnages excluded, it may be concluded that in the production of basic open-hearth steel ingots about 6,250,000 tons of new steel scrap was employed, while the consumption of basic pig iron was about 12,250,000 tons. The production of basic open-hearth steel ingots was 19,884,465 tons, leaving a difference of 1,384,465 tons. This difference represents the consumption of old iron and steel scrap and casting pit scrap, plus the ferric gains through ore additions to the bath, minus slag and other losses. The consumption of old scrap is seen to be quite small relative to the consumption of new scrap, a fact which is not universally recognized outside the steel mill. It will be understood, of course, that the proportions vary widely in different plants. At the duplex works the consumption of old material is very small, while in detached open-hearth steel works, using purchased (cold) pig iron the consumption of old material is quite large. The commonest operation, in point of tonnage, is that of combined open-hearth and Bessemer operations, in which the open-hearth furnace receives not only the scrap produced in rolling the steel it produces, but also the Bessemer scrap arising.

As the production of Bessemer steel has declined the proportion of new scrap available for the open-hearth furnace is necessarily reduced. In 1907 the production of Bessemer ingots exceeded that of open-hearth ingots by 7.5 per cent, but in 1913 open-hearth exceeded Bessemer by almost 120 per cent. There is some evidence, as indicated, that cropping has been more liberal in the past two years than formerly, and this helps to keep up the scrap supply. More recourse is had, in addition, to the duplex process, which does not need scrap badly, but the final liquidation is in increased proportions of pig iron to steel ingots produced, a fact to which reference was made in our August number, it being there estimated that, excluding the duplex steel branch, the consumption of basic pig iron was 54.8 per cent of the steel produced in 1912, and 56.9 per cent in 1913.

## Electrolytic Zinc

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—With regard to your note on the "Borchgrevink electrolytic process for the treatment of zinc ores" in your June issue (page 381) I beg to remark that the invention was not made by Mr. Borchgrevink, but was worked out by the undersigned during a study-trip in Germany. Later on the expenses, with an experimental installation, have been paid for by Mr. Borchgrevink.

If the necessary capital can be procured, the intention is in the autumn to start a greater experimental plant with a capacity of about 85 tons a day.

In this electrolytic process an anode is used which was invented by myself with a special fit-up, which prevents the formation of roughnesses and trees on the zinc. The patent is taken out in Mr. Borchgrevink's and my own name.

R. MOLSTAD.

Christiania, Norway.

## Is There a Complex Ore Problem?

*To the Editor of Metallurgical & Chemical Engineering:*

Sir—In your August issue, page 490, Mr. W. Motherwell criticizes the following remark made by me in your June issue:

"In passing, as there are fads in metallurgical lines as well as in others, I might note that we are going through a stage when the whole fraternity is on the qui vive trying to make every ore amenable to treatment by some flotation process. In the case of one-mineral separation in the United States this process has proven an aid; but it is of no benefit in the case of ores of zinc, which are truly complex, although being advocated for such. I do not know of any complex ore in Colorado, for instance, that could possibly show any advantage under this treatment."

His second paragraph brings out what he imagines is a surprise in that there are four flotation processes used in Australia.

In the third paragraph he states: "It might be worth while to have some experiments made with it," this latter statement referring to Colorado complex ore.

In the fourth paragraph he calls attention to the so-called selective flotation process.

In making the statement shown in his first paragraph I did so advisedly, proof being that only those ventures are a success with flotation which have a one-mineral separation, notably, the Butte & Superior Copper Company and the Elm Orlu at Butte, and a plant down in the Platte River country, Missouri. Of course, there are incidentally small amounts of other than the main sulphides obtained in separation, but these amounts of minerals are not quantitatively sufficient to cause annoyance.

As to his second paragraph, I was well aware of the work that has been done in Australia, as is everyone engaged in the metallurgical field. I referred in my statement only to the work done in the United States.

There is no question but that flotation will be used on the copper porphyries to separate a small amount of mineral from a large amount of gangue and will be used as an adjunct in some large plants having a large percentage of gangue and a small percentage of mineral, notably on the slime product which is a result of crushing, the tonnages here being sufficiently large to permit of one demand of the process—that there is a large enough tonnage to work upon for financial success.

Regarding Mr. Motherwell's third paragraph, I would say that I already have the proof and he admits that he has not. However, to gain his point he must present some facts which are other than surmises. Incidentally I have had the privilege of running thousands of tons of the class of ore mentioned. Our ores, as a rule, are rather coarsely crystalline so that it is not a difficult matter to make a proper separation by ordinary mechanical means, and incidentally I would also say that such ores do not have a large percentage of gangue.

Further, there have been at least two plants in Colorado which have been built to operate by some flotation process, these being more or less experimental on a large scale. There is no tonnage of a smelting grade of zinc blende being produced by either operation and yet the experiments have cost, no doubt, a sum of money sufficiently large to be noticeable.

I myself have had to do with some experimenting on Colorado ores and ores from other states and so far have found it advisable on the truly complex ores to only recommend the flotation process as a subsidiary to the other general operations, that is, where the tonnage is sufficiently large to furnish an amount of suitable material for such operation.

With respect to Mr. Motherwell's fourth paragraph, it would seem as if up to date this selective flotation process was a matter requiring "fine-haired" operating efficiency and also would be very expensive, in which case, by comparison, it would not return as great a net profit to the mine, no doubt, as the ordinary older means of mechanical separation.

Since the proofs of my statements are evident and since Mr. Motherwell does not even admit familiarity with the situation, I would suggest that he furnish proofs against my statements. Otherwise there is no argument.

LEWIS B. SKINNER.

Denver, Colo.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Since writing you on this subject I have found time to read Mr. Ionides' contribution in your June issue. He speaks of an ore containing about 5 oz. Ag. per ton, 14.5 per cent Pb., 13 per cent Zn. and 0.25 per cent Cu., and refers to the heavy penalty exacted by the smelters for the zinc.

Assuming the lead and zinc to be in the form of sulphide, any person who would send this kind of ore to a smelter deserves all he gets. The flotation process will, by itself or in conjunction with mechanical concentrators, give him two separate marketable concentrates—one containing the lead and the other the zinc.

The assay given above represents roughly the value of the sulphide ore now being mined at Broken Hill, and not a ton of it is smelted in the crude state, and has not been for at least fifteen years. Before the flotation processes were used on a commercial scale, ten years ago, the ore was concentrated by jigs, tables and vanners, the lead and some of the silver recovered, and the tailing containing the zinc and some lead and silver was accumulated pending discovery of a method of treatment.

I should perhaps have explained in my previous letter that the complexity of Broken Hill ore arises, not so much from its metal contents, as from the nature of the gangue which is largely composed of rhodonite and garnet, which have about the same specific gravity as blende.

Further on, Mr. Ionides says: "No instance is known to me where high recoveries of all metals are made from an ore containing lead and zinc, copper and zinc, or all three." At the Broken Hill South mine during the second half of 1913 (according to the *Mining and Scientific Press* of May 9, 1914), the total extraction was 91 per cent lead, 85.6 per cent silver, and 84.2 per cent of the zinc. What has Mr. Ionides to say to that? The recoveries at some other Broken Hill mines (Proprietary, North and Central) are about the same.

He also says "the shine product from a lead or copper ore certainly is refractory." This was true ten years ago, but to-day nothing is easier. The same may be said of his remark that "the presence of zinc in an ore gives trouble all the way down the line, and if recovered with the lead it becomes a liability and not an asset."

His objection that flotation will not separate two minerals, I have already answered in my previous letter.

It appears to me that the possibilities of flotation are not fully realized in this country.

W. MOTHERWELL.

Humboldt, Arizona.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—If we admit that the fine-grained ores composed of lead, zinc, and copper sulphides which have hitherto not been successfully treated on a commercial basis—excepting for the recovery of one metal—are "complex" ores, then there *is* a complex ore problem.

Some few years ago I went down to Cardigaushire, Wales, to examine a concentrating mill and tailings from same and ore from the mine. I found stacked a quite big pile of "seconds" from the tables which assayed Cu 7.5, Pb 11.8, Zn 25.5, Fe 9.9, S 28.5, CaO 5.6. The CaO was due to calcite gangue. There was no complex ore here, however, as in the mine a hand separation could have been made. I sampled a 6-in. vein of blend carrying 64.5 per cent Zn and the Pb occurred as 3-in. vein pure galena. The copper and iron were associated.

Such ores as of the Hercules-McRead district of Tasmania I would call "complex" and their successful treatment still awaits solution. Typical "Hercules" sulphide ore from No. 5 level: Cu 0.3, Pb 10 per cent to 12 per cent, Zn 26 per cent to 30 per cent, Fe 11 per cent, Mn 1.5 per cent, S 30 per cent, insoluble 10 per cent.

A really fine example of an ore worthy of the name "complex" is to be found in that probably forgotten mine, "Lake George," N. S. W., where such brilliant smelting work was done in 1899 by A. W. Hudson, now in Douglas, Arizona, a 27 per cent copper matte at first fusion being made from an ore under 2 per cent copper. At the 400-ft., 500-ft. and 600-ft. levels the ore body is about 40 ft. wide and every pound of it goes to the smelter. It is one of those close-grained sulphide ores in which no distinguishable minerals are visible. A government analysis of the 400-ft. level ore gives: Cu 1.1 per cent, Pb 8.0, Zn 14.5, Fe 17.7, $SiO_2$ 23.7, CaO 0.4, MgO 0.65, Pb $So_4$ 0.32.

My analysis of the "bulk ore" as sent to the furnaces towards the end of the smelting campaign runs: Cu 1.25 per cent, Pb 9.7, Zn 13.2 Fe 22.2 $SiO_2 + Al_2O_3$ 21.5, CaO 1.6, S 29.5.

This was sweetened up with some ores from upper levels and adjoining mines, one example being Cu 5, Pb 11.5, Zn 18.6, Fe 15.7, insoluble 17.2, CaO 0.5, S 29.5. There is a chance for the lead and zinc experts.

As other examples of what may be called complex ores I would mention those of the Conrad district of New South Wales, Bethanga and Cassillis districts of Victoria and the Oonah of Tasmania.

Mention of the Lake George mines reminds me in view of the present boom in leaching and recovery by scrap iron that it may not be known that as far back as 1899 many tons of copper were recovered from this mine from mine water. A much greater recovery might have been made had the management been awake, but the chemist's importunities were futile until backed up by threatened action for the loss of a cow that died from drinking the water 1 mile below the mine; and also a general outcry from the inhabitants of the township, whose water supply—drawn from wells sunk near the creek—gave a pale green shade to all clothes on washing day. That water carried 250 gr. per gallon.

## Cost Accounting as a Branch of Accounting, and the Work of Accountants

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—Mr. Justin H. Haynes' article in your July issue regarding unit cost keeping in metallurgical work is deeply interesting. He emphasizes "that the cost statistics and cost sheet are a comparative guide to the maintenance of efficiency in a plant controlled or supervised by any executive."

This is the traditional and accepted definition of a cost sheet, and accountants universally are striving with considerable measure of success to make it so, and to make the figures that are placed thereon the true and actual showing for any period under review.

As I am in opposition to Mr. Haynes, as to who should draw up costs accounts, I would like to place before him through the pages of your paper Cost Accounting from the Accountant's standpoint and to show the necessity to *both the operator* and the administration, of the cost accounts and the fiscal books being in unison. This I will try and do, also endeavoring to convince him that the accountant is the most necessary friend of the operator, both in translating his desires and in placing before him those figures and statements which will furnish him with all the true figures that are requested of him, and which will also be in perfect harmony with the financial section of the company's books.

My views are:

Cost-accounting records, though perhaps only indirectly related to bookkeeping records, must be founded on ordinary double-entry principles. It may be sufficient for the financial records to show the total amount of the payroll, for example, whilst for the superintendent's cost sheet this item on the financial books will have to be dissected, and in consequence of obtaining this dissection from the financial records it will be a detail of these financial records. In other words the cost accounts must be in concord with the financial records, if for no other reason than the double check it affords both systems (and in consequence the greater security the operating man can feel in reviewing his figures).

Further cost keeping must be part and parcel of the whole accounting system for the reason that both use data that are alive in both. For whilst financial bookkeeping generally considers the operations of an organization, cost accounting considers the operations in detail. Both have to do with resources, liabilities, receipts, disbursements, losses and gains. And the fact that all these headings enter into both cost accounting and financial book-keeping, and that the former will have to look to the latter for its division of same shows only more clearly that it is impossible to draw any distinct line between them. They are an entity.

The man to advise and install a system of cost accounts should be a technical statistician who understands and studies the requirements and methods of manufacturing, etc. This the members of the accounting profession are rapidly becoming more and more to be.

In this installation, accountants readily recognize that it is most necessary for the cost systematizer to cooperate with the engineer if an efficient and practical cost system is to result. Obviously a superintendent knows along what lines he wishes information, and as the results are of primary importance to the engineer, that person should suggest these lines; but the accountant is the better suited to determine the means, the procedure and forms in connection with acquiring these data, as well as of distributing and segregating same, inasmuch as it is the accounting profession and not the engineering profession that has concerned itself with the study of cost systems together with their many deep and vexed problems (operating expense burden being an example). This study of cost accounting by accountants has not been given for the purpose of giving information to directors (excepting where a problem of cost accounting attaches itself to the desire of directors to test the efficiency of the superintendent or his subordinates), but for the purpose of giving the superintendent the benefit of a more scientific interpretation of the proper division and application of certain facts.

I would lay strong stress on the parenthesis above, to draw out the fact that the operator is not the only one interested in his cost figures, but that his executive is also so interested, when the accountant, who is independent of the operator, vouches for the figures shown, they will certainly have more weight than if the operator makes them up in his own way, and if they are diversant from the financial or accountant's books.

The degree of finesse to which any cost system can be installed is determined by the wishes of the superintendent, but it should be also determined by experience. Expense is also often a consideration.

If (as doubtless it will be, where applicable) the unit cost system is desired, it could be and has been as readily installed in stamp milling as it has been used elsewhere, in flour mills, cotton mills, steel mills, railroads and public utilities, etc., by accountants.

To say that the accountant is not interested in the unit cost, is to exaggerate slightly. It is his duty to be interested in that, and in any other thing in the line of accounts that any individual requires. And further, as the unit cost is determined by the "dollar and cents" costs, he will undobutedly have an endless chain of interest as long as costing is the subject.

An example of how the accountant is interested in the operating figures and the financial figures at the same time is this: Assume a milling company purchasing various parts of machinery, to be installed, worth say $1000. The operator having no books is compelled to write it all off in his cost sheet in the first month, instead of being able to open a "suspense account" and proportion this charge reasonably over the proper life of the machinery. Inasmuch as this will affect the profit and loss account of the company in the month it is written off, and also in the subsequent month it should have been written off, it is interesting to the financial end, more especially as the possibility is that with a large concern, the $1000 item mentioned above will be manifoldly increased.

In fact in many more ways than this the operator (if unattached to the financial department of the concern) can be responsible for unreliable statements of the company, as well as cost sheets that would deceive himself.

I think the particular reason that poor results are often obtained, is the fact that many engineers are too prone to belittle the intelligence of the accounting department, and to consider this department as "only a necessary expense to be kept as low as possible," and that they therefore are too ready to employ cheap material instead of obtaining men with experience, training and intelligence in cost accounting. Mayhap Mr. Haynes has been in environments of this character, and it is to be regretted that this state of affairs exists.

It should be the keynote of both the engineering and accounting professions in regard to cost keeping, to submerge their own and their departmental antagonisms, and co-operate in a friendly business way to both design and carry out costing to the beneficial health of the whole corporation of which they are units.

The operator may feel that "errors are creeping into the very foundation" of his data, and "that exact distribution is unobtainable." This can certainly be remedied by his getting together with the accounting department and co-operating with them to put in the proper forms and system that will give him absolutely reliable information.

The cuts that Mr. Haynes has displayed are interesting as examples of what are especially adapted to his requirements, but are only synonymous with like information obtained from systems installed universally by accountants.

In conclusion, I would say, that the field of cost accounting is so broad and varied that it behooves all of us to broaden our viewpoint and knowledge for the betterment of all concerned, and it is treason to intelligence to infer that a chemist (for example) can have knowledge of chemistry and nothing else, or an engineer of engineering and nought else, etc., etc., or that nobody else can be of use to him even in his own sphere. He should rather be prepared to interest others in his work. Only with a viewpoint of unity can it be possible for the executive-in-charge to arrive at the best reliable information regarding the cost accounting placed before him—that is by the joining of the ideas of the accounting and engineering staff, and the relating of the costs to the financial records.

## Toronto Meeting of American Chemical Society Postponed

The meeting of the American Chemical Society which was to be held in Montreal, Canada, in September, has been indefinitely postponed on account of Canada being involved in the European war, and it now seems improbable that any meeting of the Society will be held this fall for the reading of papers. The present outlook is that the next meeting of the American Chemical Society will be in New Orleans, April 1 to 3, 1915.

The **American Foundrymen's Association** and the **American Institute of Metals** will hold the annual meeting in Chicago from September 7 to 11. The program of the American Institute of Metals comprises joint meetings with the American Foundrymen's Association on Tuesday and Wednesday, 10 a. m., and separate meetings on Tuesday, 2 p. m., Thursday, 10 a. m. and 2 p. m., and Friday, 10 a. m. On Monday evening the Foremen hold a banquet at the La Salle Hotel, and on Thursday evening the American Institute of Metals holds a meeting at the same place.

# The European War and the Chemical Industries of This Country

The European war is affecting the chemical industries of this country in the most varying phases. To get a clear view of the situation, Metallurgical and Chemical Engineering has interviewed a few men, prominent in American chemistry. To serve as a general guide the following questions were asked:

1. How does the cutting-off of the supply of certain raw materials by the European war affect the continuity of operation of the various chemical industries in this country? Can any of these raw materials be procured in the United States so as to make our industries independent of other countries? What is the situation of the potash industry?
2. Will the forced industrial restriction in Europe, if it continues long enough, warrant the development in this country of chemical industries which have so far been almost exclusively European? What are the possibilities of an American coal tar industry?
3. In the case of a long continued war, do you think that the personnel of the American chemical and metallurgical industries will be affected? Do you think it possible that there may be a scarcity of chemically trained men or of unskilled workmen?
4. Is there enough demand in South American countries for products of the chemical industries to make exports from this country worth while and open new markets for the chemical industries of this country?

* * *

## Interview with Dr. Wm. H. Nichols

CHAIRMAN OF THE BOARD, GENERAL CHEMICAL COMPANY; PRESIDENT, NICHOLS COPPER COMPANY; PAST PRESIDENT OF THE SOCIETY OF CHEMICAL INDUSTRY; AND PRESIDENT OF THE EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY, 1912.

In an interview given to the Editor of Metallurgical and Chemical Engineering on August 21, Dr. Wm. H. Nichols stated that at the present moment no one is in position to arrive at definite conclusions concerning the effect on this country of the European war, as conditions are rapidly changing day by day, and past events have given us very little on which to base present conclusions. He emphasized the fact, however, that we had certainly learned that it was unnecessary for the American business man to worry; that patience and calmness would be amply repaid in the better frame of mind in which the Americans would approach the thousands of new problems which are constantly arising, and which will, of course, have to be solved.

The European war will put the American chemist on his mettle, and he will certainly arise to the emergency and demonstrate that he is made of the right stuff.

In reply to the four specific questions given above, Dr. Nichols stated as follows:

1. The supply of raw materials, as far as the field of heavy chemicals is concerned, would appear to call for no alarm and comparatively little uneasiness. Pyrites, nitrate of soda, and material of that kind, though coming largely from Spain, South America and other foreign ports, seem to be arriving with considerable regularity, and should not seriously jeopardize those chemicals used in the manufacturing of the first chemical raw material. Stassfurt potash supply, upon which the world depends, is, of course, entirely cut off. The American farmer may have to get along for the time being without potash fertilizers; but other substitutes will take their place for the present. Potash for other industries used in smaller quantities may be secured from sea weed or feldspar. Necessities will develop other sources of supply than the German mines. With the chemicals that this country has depended upon Germany supplying, covering a wide range from certain salts, such as epsom salts made from kieserite, which industry Germany has entirely stifled in this country, through to finished dyes, which have never been made in quantity outside of the large German factories, it is too early to state what America will do; but it is safe to say that most of them we can get along without when necessity dictates.

2. The prospect of the American coal tar industry will depend very largely on the encouragement which the American buyer will give to the American manufacturer. The experience of the Benzol Products Co., which started in a small way to manufacture aniline oil in this country, illustrates the attitude that Europeans have always taken where Americans have tried to parallel their manufacturing experiences. They decided that the American plant must be killed off, and although a tariff of 10 per cent was placed on aniline oil by the Democratic Congress, foreign manufacturers reduced the price to a point where it was impossible to compete. It has heretofore been found impossible to secure encouragement for certain lines of manufacture here from the buyer of chemicals, and it is largely through the desire of the American purchaser to secure his goods at the lowest possible price that the color industry has not been able to get a foothold. The development of this branch of the chemical industry is, therefore, entirely in the hands of the buyers, and no manufacturer can predict what is likely to come out of the present curtailment of imports of necessary chemicals to this country.

3. A scarcity of trained chemists or unskilled workmen seems to be at the present time entirely out of the question, although it is, of course, hard to foresee what technical knowledge will now be called into use.

4. The South American market for chemicals is an important one, and though it is not yet developed, it may be expected to grow into an important outlet for American products. The difficulties of doing business in South America has largely been caused by lack of proper banking facilities, and it is only after this problem is solved that we may turn to the Southern republics as large consumers of our products.

With regard to the copper market, he stated that the situation was quite remarkable, and that the producers had for the first time in their history been unanimous in showing a large amount of common sense. All copper mines had reduced production by 50 per cent or even more and the refineries had, of course, followed suit, the Nichols Copper Company plant being run at present at about 50 per cent of its capacity. As, approximately, one-half of the copper produced has heretofore gone abroad, this curtailment should make it possible to provide for all of the local requirements, so that when the war is over the metal should be in a good and strong position.

He again emphasized that in this crisis the American copper men have shown more sense than ever before, and that they had been absolutely unanimous.

In summing up, Dr. Nichols took a very reassuring view of the whole situation. He admitted that it would be necessary to readjust ourselves to new conditions, but that in his opinion American ingenuity will solve most, if not all, of the problems as they arise.

He gave as an example of American resources—the sugar situation. As the price goes up, glucose or corn syrup will take its place in many fields. Glucose cannot, of course, replace granulated sugar, but it most certainly will add a cheap substitute for sugar in many household uses.

The interruption of the shipment of jute to this country had also called for the ingenuity of the American manufacturers, who are in some places replacing rough cotton bags for the heretofore indispensable jute bags.

He considered that there would be no danger of lack of necessities of life, but that the extravagances of the last few years might have to be restrained.

It would appear from our interview that Dr. Nichols considers this a great opportunity for the American chemist to show what he is able to accomplish.

* * *

### Another Reassuring View of the General Situation

**Mr. Maximilian Toch** (partner of Toch Brothers) remarks that since the war was declared his firm has been working night and day, and he is of the opinion that this is the finest opportunity that America has ever had for the development of her chemical industries.

1. The cutting off of supply of certain raw materials will, of course, cripple the chemical industries for the time being. There is no doubt that matters will right themselves, because we are more or less of a pioneer nation, and a pioneer can always help himself. In the case of raw materials, it would be difficult to say exactly how many of the raw materials can be procured in the United States which were formerly imported. Of course, indigenous raw materials cannot be made excepting in the country where they are grown or procured, such as the fossil resins. Still, we are able with the aid of China wood oil and resin to do many things we could not do 10 years ago, but China wood oil, in case our supply is cut off, could be produced in time in America, for the Department of Agriculture, through the able work of David Fairchild, has planted a number of Kiri nut trees.

As regards the potash situation there are a number of methods for the extraction of sufficient potash from felspar, kelp and the like. Many of the methods, some of which are patented, have never been exploited on account of their cost, but for the present cost will not enter, and therefore we should have no fear that the supply of potash will be curtailed if we can make a sufficient quantity from many of the potash-bearing materials in the United States.

2. The forced industrial restrictions in Europe, whether they continue long enough or not, by all means warrant the development in this country of many of the chemical industries which we have slighted in times gone by. With the exception of the patented coal tar colors, Mr. Toch sees no reason why all the others should not be made here, and as near as he can glean, two concerns are already starting in to erect installations for the purpose of making many of the coal tar colors which have heretofore only been made in this country on a small scale.

3. "I do not consider that there will be a scarcity of chemically trained men or skilled workmen in the case of a long continued war. Opportunity always brings out the best that there is in us, and in my own case I have advanced some men owing to sudden increased business and feel that they will fill the positions capably.

4. "There is a sufficient demand in South American countries for the products of the chemical industries to make exports from this country worth while. In the paint, varnish and chemical industry very few materials have ever been exported to South America. It is just three weeks ago since hostilities became general, but within the last three weeks our firm has received two substantial orders from South America from a district where English and German competition has prevented us from selling."

* * *

### Interviews on the Coal-Tar Industry

**Mr. William J. Matheson** (president Matheson Lead Company, vice-president Corn Products Refining Company, director American Cotton Oil Company, Benzol Products Company, Cassella Color Company, General Chemical Company) comments on question (2) as follows: "In regard to the organic chemical industries, especially the primal products, such as aniline oil, aniline salts, beta naphthol, paranitro aniline, etc., the industry is already developed, and its growth depends in large measure upon the supply of cheap benzol. These products are made by the Benzol Products Company.

"As to coal-tar colors or dyes, I would not attempt to add to the able paper[*] that has been presented on this subject by Dr. Hesse."

* * *

**Dr. B. C. Hesse** (chemical engineer and expert, 90 William Street, New York City) comments on question (2), with special reference to the coal-tar industry, as follows:

In the coal-tar industry the following three divisions may be made for convenience and clarity:

I. Products from coal-tar by distillation, expression and like operations.

II. Products obtained from I by chemical transformation but not themselves dyes.

III. Dyes made from II.

I and II make up practically all of paragraph 536 of the United States Tariff of 1909.

According to what purport to be official German figures Germany's foreign trade in 1913 in these three classes was as follows (in metric tons):

| | Imports into Germany | Exports from Germany | Excess of Exports over imports |
|---|---|---|---|
| I ........ | 67,501 | 342,893 | 275,392 |
| II ........ | 673 | 16,311 | 15,638 |
| III........ | 3,238 | 163,874 | 160,636 |

Obviously division I need not be further considered. As to division II the German figures are given in three subdivisions:

(a) Anilin oil and salt.

(b) Naphthol and naphthylamin.

(c) Anthraquinone, nitro-benzol, toluidin, resorcin, phthalic acid and other coal-tar products.

For division III the German figures are given in four subdivisions:

(d) Aniline dyes.

(e) Anthracene dyes, other than Alizarin red.

(f) Alizarin red.

(g) Indigo.

At present the United States produces about 30 per cent of its requirements of aniline dyes (division III), but almost entirely from materials of division II brought from Germany.

The key to the situation lies in division II and in this Germany controls the world's markets. This control is due to the facts that while the growth of this division was relatively slow, yet the field has become very much interwoven, each of its hundred or more products are dependent upon or made up of one or more other products, no one of them is of use without still others; the industrial and commercial conditions or relations have grown with the technical development so that the coal-tar dye industry is really a conglomerate of many separate parts acting and reacting upon each other, commercially and industrially.

---

[*] This paper is printed on p. 581. See also the following interview.—Editor.

Not a single one of the 22 factories in Germany is wholly independent of other factories in Germany, whereas together they are independent of sources outside of Germany, or can very readily be so should occasion arise. It would not do merely to transplant even the largest German works to this country; a part of probably each German works would be necessary to produce here or anywhere a complete and self-contained industry. Such a transplanting of the coal-tar dye industry would be comparable to an attempt to transplant to this country *every single branch* of, say, the textile industry or any other highly ramified and diversified art.

Germany's supremacy in this field has been for more than 30 years a standing challenge not only to the chemists and capitalists of the United States but to the chemists and capitalists of all the rest of the world as well. Except Switzerland, no country has succeeded in selling Germany more coal-tar dyes than it buys from Germany, but all of them *without exception* buy more of intermediate products, i. e., division II, from Germany than they sell Germany.

The seven European countries other than Germany noted for their chemists and having a large and flourishing chemical industry are Austria, Belgium, France, Great Britain, Italy, Russia and Switzerland. Their indebtedness in metric tons to Germany, together with that of the United States, for 1913, the countries being arranged in the order of their total indebtedness which is distributed over the seven items, follows:

| | Division II | | | Division III | | | | |
|---|---|---|---|---|---|---|---|---|
| | a | b | c | d | e | f | g | |
| | Anilin Oil | Naphthol and Naphthylamin | Anthra Quinone, etc. | Anilin Dyes | Varicolored Alizarins | Alizarin Red | Indigo | Net Totals |
| 1. United States | 2,428 | 638 | 965 | 13,855 | 2,164 | 493 | 3,461 | 24,004 |
| 2. Great Britain | 340 | 333 | **34 | 10,793 | 1,130 | 1,493 | 1,180 | 15,235 |
| 3. Austria | 655 | 109 | 284 | 5,582 | **223 | 207 | 1,361 | 7,975 |
| 4. Italy | 650 | .... | 825 | 4,097 | 158 | .... | 662 | 6,392 |
| 5. Russia | 602 | 1,117 | 998 | 1,098 | 156 | 174 | 434 | 4,579 |
| 6. Belgium | 120 | .... | 108 | 2,400 | 96 | .... | 313 | 3,037 |
| 7. France | .... | 217 | 776 | 1,301 | 124 | 98 | 323 | 2,839 |
| 8. Switzerland | 1,217 | 272 | 1,201 | **941 | .... | 259 | .... | 2,008 |
| Net totals | 6,012 | 2,686 | 5,123 | 38,185 | 3,605 | 2,724 | 7,734 | 66,069 |
| Number of countries Germany exported to | 11 | 6 | 11 | 32 | 12 | 9 | 21 | |

Summarized by divisions II and III the results are:

| | II | III |
|---|---|---|
| United States | 4,031 | 19,973 |
| Great Britain | 639 | 14,596 |
| Austria | 1,048 | 6,927 |
| Italy | 1,475 | 4,917 |
| Russia | 2,717 | 1,862 |
| Belgium | 228 | 2,809 |
| France | 993 | 1,846 |
| Switzerland | 2,690 | ** 682 |

**Credit

According to the latest information available the number of coal-tar dyestuff works in the world and their geographical distribution in 11 countries is as follows, in the order of their number of factories: 22 Germany, 11 France, 11 Great Britain, 9 United States, 4 Austria-Hungary, 4 Switzerland, 2 Holland, 2 Russia, 1 Belgium, 1 Greece, 1 Italy.

In the course of the development of this business 16 plants that made coal-tar dyes have abandoned that work, 11 in Germany and one each in Austria, Belgium, France, Great Britain and Switzerland. Fourtenn have been absorbed by others, six in Germany, four in Switzerland, two in France and one each in Belgium and Holland.

Where these seven countries together have failed so signally it cannot be fairly urged as a fault of the chemists of this country that they have not succeeded.

There is another side to this, namely, the investor's side. A self-contained and complete coal-tar dye industry in this country would to-day call for preparedness to make about 700 different dyes. In the fiscal year 1913-1914 this country imported indigo to the extent of $1,093,226, alizarin to the extent of $815,459, both of which are without tariff protection; $7,464,134 worth of aniline dyes with a duty of 30 per cent and aniline oil with a duty of 10 per cent. This means 700 different aniline dyes would average a gross annual income each of about $10,000. To introduce 700 different sets of operations and perhaps half that many different sets of apparatus at *one time* to produce on the average for each set of operations a gross of $35 per day can hardly be regarded as an attractive proposition when the initial lump gross outlay would be not less than $5,000,000 actual cash. Each of these 700 products requires good manufacture from the start because good qualities of each are already on the market. It is one thing to grow and develop such an industry or art and to maintain it against newcomers, but it is quite a different thing to build it up afresh and in its entirety in the face of competition and to hold it against those who developed the business, know all its ins and outs, have their experience and plant bought, paid for and written off long ago. It could hardly be expected that if successful this would employ as many as 7000 people all told and the gross makes out less than 0.4 per cent of our total import business.

With unlimited and immediately available capital the American chemist can build up such a complete industry, but the dividends would be a long way off. Capitalists, American or otherwise, do not take kindly to such handicaps or obstacles, and justly so.

The truth seems to be that the whole of this industry cannot be successfully transplanted and attempts to transplant part only have not resulted in any self-contained and independent industry anywhere but in a thing whose real roots are still in German soil and if it could be transplanted as a whole the net result would not be commensurate with the expense, effort and risk connected with it. What portion or part if any, and the equivalent of a complete and self-contained industry for all the domestic needs of this country could ultimately be transplanted here is a problem that has had the serious attention of competent chemists and capitalists in this country for many years without a definite or satisfactory answer thereto having been arrived at. If the present conditions will contribute to a solution thereof cannot be decided out of hand, the first impression certainly is that they will *not* so contribute.

Dr. Louis J. Matos (of the technical staff of the Cassella Color Company) points out that the question is: *Can* aniline dyes be made here in the present emergency, and in sufficient quantity and variety for our mills?

The question is not, primarily, whether we have the necessary complement of those "highly specialized and trained chemists" always connected with the dyestuff industry in discourses, but whether we produce a sufficient quantity of coal tar to make us independent of any foreign source of tar, and also whether higher prices cannot be obtained for certain tar distillates and fractions from commercial outlets other than the color industry could afford to pay.

Immense quantities of naphthalene are consumed here in the form of "tar camphor," and it is probable that much of this is available from tars produced here, and which could conveniently serve as a most valuable raw material or starting product for a most extensive series of dyes of which it is the base.

Lower fractions of the tar distillates, including *toluol*, are undoubtedly produced here, and in this case we have another initial raw material for a wide range of dyes.

Patent matters in connection with the dyes are of great importance, and for the extension of the tar color industry here the expired patents of still useful dyes would be made first.

To my mind it is not so much a question of inability of our chemists to produce dyes; for I believe that those trained in *practical* organic chemistry (not necessarily research chemists) would in a short time grasp the situation quickly, but it is a question of the *temporary handicap of not having the especially designed and constructed appliances* that are necessary for the proper conduct of the technical operations in elaborating the several raw materials to middle and ultimate products.

Here is the familiar example of benzopurpurine 4 B, one of the most common cotton dyes; starting with *toluol* and gradually converting this into *tolidine* means four chief processes made up of a succession of minor operations, thus: Toluene is nitrated, kept cool, and then distilled, the resulting nitrotoluene is reduced with zinc and caustic soda, yielding hydrazotoluene which is in turn broken up with muriatic acid, giving us the tolidine, which we combine with naphthionic acid, which is also the end product commencing with naphthalene, and converted in turn into nitronaphthalene, then naphthylamine, and finally naphthionic acid.

In the foregoing, no mention is made of the appliances that must be installed for the particular purpose of working the chemical reactions.

The problem is to provide for the chemical engineers' side of the factory work, and with a proper conservation of our own tars, it is not impossible that a wide range of colors might be produced here.

To found an industry is, however, quite a different matter from starting a factory, and for an industry to proceed orderly, requires that there must be at hand raw material and the constructive engineering ability to take care of the elaboration, and in this particular industry our American machinists and constructors have not been called upon to show what they can do.

## The Iron and Steel Market

All the iron and steel producing countries of any consequence, with the sole exception of the United States, are engaged in the fiercest and most destructive war of all time. The countries at war are those that have been engaged in financing the development of non-productive but consuming countries, these countries having of late been taking from the producing countries upwards of 10,000,000 tons of finished steel a year, besides large quantities of machinery, hardware and cutlery, involving perhaps a couple million tons in addition. Of the total tonnage the United States has been furnishing about one-fourth.

A condition is presented the effects of which are impossible to gauge. There is no experience to guide, and the situation is so new that thus far it presents no trends that can be studied to advantage.

To add to the complexity, the iron producing countries at war are differently affected. Germany is hemmed in and cannot pursue her foreign commerce. England seems able shortly to resume her commerce, so far as ocean transport is concerned, but may be crippled in actual production through shortage of men, and perhaps also of certain raw materials.

The desire for commerce was at the root of this war, and it is natural and consistent that England should now endeavor to continue and even, if possible, expand her commerce. The United States is equally disposed to expand its commerce, but instead of being able at once to begin expanding, is confronted at the outset with a lack of ocean transportation facilities to continue the commerce already acquired, and is faced with the prospect that the so-called "neutral markets," through the withdrawal of European financial accommodations and a complete tying up of the mediums of international money exchange, are unable at the moment to buy.

At the first announcement of war the steel trade of the United States appeared to embrace the conclusion that an immediate and large demand would spring up for its products, but it required only a few days of observation and consideration to develop that the most serious difficulties lay in the way.

A problem serious in itself arose from the shutting off of imports of ferromanganese, manganese ore and Austrian magnesite. Ferromanganese, which had been readily available at $37 for German and $38 for English, f. o. b. Baltimore, jumped to $140 or $150 for odd lots to be shipped from surplus stocks, though a decline has since occurred to a trifle above $100, there being promise of an early resumption of shipments from England, though possibly on a restricted scale. Eventually there may be larger imports than formerly of manganese ore from Brazil and India. For magnesite a substitute, however expensive in the use, will doubtless have to be found.

The domestic trade of the United States has been affected in various ways. There has been some tendency on the part of buyers to take early deliveries from mills, on contracts made at recent minimum prices, through fear of a possible shortage later, while on the other hand there has developed a strong feeling of conservatism as to fresh purchases. New projects that require financing have been indefinitely held up.

What has occurred thus far since the war started is probably no index of what may follow. Early in August prices of bars, plates, shapes and sheets were advanced, largely as a precautionary measure on the part of the mills, faced by higher prices for ferromanganese and the possibility of a labor shortage, and additional advances are predicted. The wire advance of August 21 did not grow out of the war, but was a sequel to the advance of July 20, advances in wire products, on account of the peculiar manner in which the wire market is conducted, usually being made in multiple. Steel prices in general may advance further as the war progresses, but there is no clear indication thus far that such will be the case.

As to domestic demand, the total has not thus far been materially reduced, but as work in progress is completed there may be a decided slackening.

As to exports, the first war effect was to shut off the movement entirely, through there being no ocean movement and no means for payment. The first step is to restore exports to the former volume, the second being, if possible, to increase the volume, and that second step may not be reached for months. That the building up of an export trade will be slow is suggested by the fact that our exports to Canada have been decreased, instead of being increased by the fact that British exports to Canada were immediately, though presumably only temporarily, shut off. Indeed, the Canadian steel manufacturers themselves have decreased their production.

As to domestic trade, it is significant that while some fairly large railroad buying was expected to follow a decision in the eastern rate case, rendered August 1, the fact is that orders for only 2,000 freight cars were reported during August, when the monthly average during the first seven months of the year was about 10,000 cars.

The steel mills operated during August at about 65 per cent of capacity, or at about the same rate as in July, when the prospects had been that operations would steadily increase. At the moment the prospect is that September output will be less rather than more than the August output.

### Pig Iron

The pig iron market has been practically stagnant during August, and the seaboard markets, relieved of the fear of imports, have been unable to stiffen. Deliveries have shown practically no change, but it is uncertain whether they can be maintained indefinitely. Prices are largely nominal, and are quotable at little variation from those of a month ago: No. 2 foundry, f. o. b. Birmingham, $10 to $10.25; delivered Philadelphia, $14.25 to $14.50; f. o. b. furnace, Buffalo, $13 to $13.50; f. o. b. furnace, Chicago, $14; f. o. b. valley furnaces (90 cents higher delivered Pittsburgh) Bessemer, $14; basic, $13; No. 2 foundry and malleable, $13 to $13.25; gray forge, $12.50 to $12.75.

### Steel

The mills have marked up quotations about $1 a ton since the war, the advance being based partly upon higher prospective costs, and it is asserted in some quarters that further advances will soon be made. Consumers are fairly well covered by old contracts. The market is quotable at $20.50 and $21.50 for billets and sheet bars respectively, f. o. b. maker's mill, Pittsburgh, and at $20 and $21 respectively at maker's mill, Youngstown, rods being about $26, Pittsburgh.

### Finished Steel

Finished steel prices are firmly maintained, in most cases at advances from quotations of a month ago. Prices quoted below are for prompt shipment, fourth quarter shipment being as a rule $1 or $2 a ton higher. Quotations are f. o. b. Pittsburgh, unless otherwise stated, with full freight to point of delivery, and the Chicago and eastern markets are practically on this basis, concessions of part of the freight having practically disappeared.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f. o. b. mill, except Colorado.

Plates, tank quality, 1.20c.

Shapes, 1.20c.

Steel bars and bands, 1.20c., base.

Iron bars, 1.25c., Pittsburgh; 1.17½ to 1.22½c., Philadelphia; 1.07½ to 1.10c., Chicago.

Sheets, blue annealed, 10 gage, 1.40c.; black, 28 gage, 1.90c.; galvanized, 28 gage, 2.90c.; painted corrugated, 28 gage, 2.10c.; galvanized corrugated, 28 gage, 2.95c.

Steel pipe, ¾ in. to 3 in., 80 per cent. off list.

Steel boiler tubes, 3½ to 4½ in., 72 per cent. off list.

Wire nails, $1.60, base; smooth fence wire, 1.40c.; galvanized fence wire, 1.80c.; galvanized barb wire, 2.00c.

Standard railroad spikes, 1.45 to 1.50c., Pittsburgh; 1.50 to 1.55c., Chicago.

Structural rivets, 1.55 to 1.60c.; boiler rivets, 1.65 to 1.70c.

Cold rolled shafting, 66 per cent. off list.

Chain, ⅜ in. proof coil, 3.05 to 3.15c.

---

**The American Boiler Manufacturers' Association** will hold its 26th annual convention in New York City from September 1 to 4, with headquarters at the Waldorf-Astoria Hotel. Mr. F. B. Slocum, West and Calyer Streets, Brooklyn, N. Y., is the secretary.

**The Hardinge Conical Mill Co.**, of New York City, has received a fifth repeat order from the Braden Copper Company of Rancagua, Chile, for six Hardinge mills. These mills are all 8-ft. diameter by 48-in. cyl. and are to be driven by single-reduction herringbone gears of the Wuest type.

## The Western Metallurgical Field

### The Complex-Ore Problem

In the editorial summary of the symposium on complex ores, published in our July issue, an important point suggested by one or two of the contributors was not sufficiently emphasized. The economic loss of metals, particularly lead and zinc, due to imperfect methods of separation by ore-dressing methods is an item which, in the aggregate, must be tremendous. The smelter demands concentrates of a certain grade and purity in order that he may conduct his own operations to the best advantage. This places a limitation on the ore producer who, in meeting the demand for marketable concentrates, usually finds it necessary to sacrifice high recovery. Metallurgical saving is subordinated to economic recovery, and losses accrue proportionately. Lead remaining in zinc concentrate represents an economic loss, and the same is true of zinc in lead concentrate.

An illustration of these losses was given, referring to a published statement of a Montana producer of zinc concentrate. The recovery was high—90%—and the grade of concentrate was good—50% zinc; but it contained also small percentages of lead and copper, with some silver and gold. The gross value of the merchantable metals, based on current quotations, was about $80 per ton of concentrate. The actual market value at the smelter was about $24, leaving a difference of $56. A part of this difference is accounted for in freight, smelting and marketing charges, but much of it probably represents a loss to the producer due to economic conditions in the smelting industry. Such instances emphasize the limitations of present methods of concentration and increase the demand for new processes that are more efficient.

### Dry Jigging Unsized Ore

One of the features of the Plumb pneumatic jig, described in this journal December, 1913, page 722, is its ability to produce concentrates of unusually high grade. In fact, according to the principle on which the jig operates, only high-grade, clean concentrates can be produced, and the saving is proportional to the degree in which the minerals have been unlocked in crushing. Some of the tests made by jigging the concentrates from wet tables showed the possibility of improving the grade to such an extent that their commercial value was greatly enhanced. In general, one of the advantages of the machine is that it overcomes in a large degree the economic loss referred to above in the concentration of lead-zinc ores, because the concentrates are not only of high grade, but the percentage recovery also is high.

At the time the jig was first described it was considered necessary to provide a feed that was sized within reasonably wide limits, say —12+20, —20+40 and —40+150 mesh. Ore finer than 150-mesh was not treated, as that size was considered outside the field of the machine. A recent development is that unsized feed can be treated as efficiently as sized feed, without eliminating the finest portion. This offers an advantage in avoiding the cost and trouble of sizing, as well as saving the mineral formerly discarded in the —150 mesh portion and treated on wet slime concentrators.

The development will sound illogical to those who have followed dry concentration, because sizing has been considered one of the prerequisites for successful work. But it is quite as logical as Joplin practice of wet-jigging unsized feed, where the fine mineral finds its way through the bed into the hutch, and the coarser grades accumulate on the bed and are discharged. It has been found that the same conditions obtain in a

Plumb pneumatic jig, working with a coarser screen than was formerly used. After a suitable bed has been formed coarse and fine mineral are recovered, the former at the usual discharge weir and the latter through the hutch. Apparently this is one of the cases where sizing can be dispensed with.

### Telluride's Disaster

Engineers throughout the country will regret to learn of the disaster which befell the mining community of Telluride on July 27, as the result of a cloudburst in the Sawtooth range, north of the town. The flood of water and mud which poured out of Cornet Creek canon, followed closely after a heavy rain, and covered about fifteen blocks in the central business and residential section with mud and debris to a depth of from four to ten feet. Detailed reports of the disaster tell of residences swept away by the flood, and others filled with mud and boulders. The New Sheridan Hotel, which has been the rendezvous of engineers visiting Telluride, was one of the business blocks inundated. The Commercial Club was wrecked and filled with mud to within a few inches of the ceiling. The First National Bank building also was damaged.

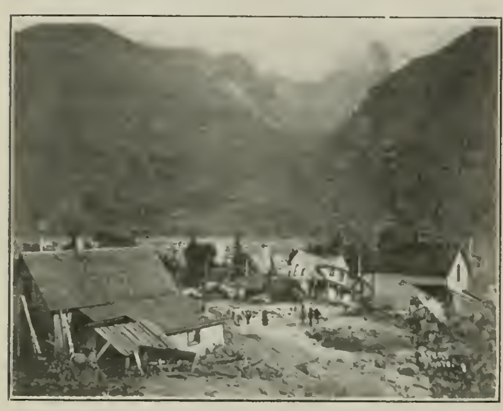

FIG. 1—PATH OF FLOOD FROM MOUTH OF CANON, LOOKING TOWARD BEAR CREEK

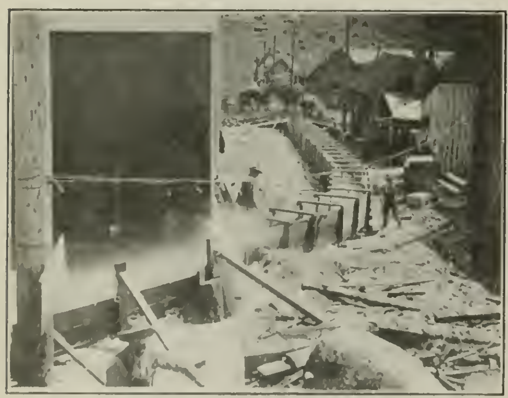

FIG. 2—SLUICE CONSTRUCTION

Immediately following the storm, a committee headed by Mr. Charles A. Chase, manager for the Liberty Bell Gold Mining Co., laid plans for cleaning the town. A flume was constructed through the inundated section, and by the aid of the water from Cornet Creek and the local water system the accumulation of mud was sluiced to the San Miguel River. It will be several weeks before the tremendous volume of mud and debris can be removed.

The flood occurred about one o'clock in the afternoon, which possibly accounts for the fact that but one fatality resulted. The loss is estimated at about $200,000, sustained by residents and business houses. The local mining companies contributed liberally to a relief fund, but it is likely that offers of financial assistance from other sources outside Telluride will have to be accepted.

### Purchase of Aurora Consolidated

The Goldfield Consolidated Mines Co. has issued an official statement regarding the terms of its purchase of the property of the Aurora Consolidated Mines Co., at Aurora, Mineral county, Nevada. The Goldfield company purchased 592,000 shares, equal to 87% of the issued shares of Aurora Consolidated, at a price of $1.28887 per share, or on the basis of $877,075 for the entire issue. Cash paid on June 25, the date of purchase, was $388,800; three subsequent payments of $100,000 each, with interest at 6% per annum were arranged for at thirty-day intervals, and the final payment of $74,211 is tot be made on October 25. At the time of the purchase, mining and milling equipment with an estimated capacity of 500 tons per day was practically completed and ready for operation. The estimated net value of fully and partly developed ore, after deducting estimated cost of realization, was $893,000. The developed ore has a gross value of $4.81 per ton, from which it is expected to realize a net profit of $1.50 per ton by cyanidation. Owing to the disbursement of a large sum in this purchase, the Goldfield company has omitted its usual dividend payment.

### Calumet & Hecla to Leach Tailings

Although no details are available at the present time, it is understood that the Calumet & Hecla Mining Co., Michigan, is planning to leach the tailings from its new regrinding and reconcentrating plant. Tailings from early concentration are to be dredged from Lake Linden, reground in Hardinge mills and reconcentrated. The tailings will then be classified in Dorr classifiers of special design, and the sand product subjected to a leaching process to recover the contained copper.

## Some Aspects of Industrial Chemistry*

BY DR. L. H. BAEKELAND

While I appreciate deeply the distinction of speaking before you on the occasion of the fiftieth anniversary of the Columbia School of Mines, I realize, at the same time, that nobody here present could do better justice to the subject which has been chosen for this lecture than the beloved master in whose honor the Charles Frederick Chandler Lectureship has been created.

Dr. Chandler, in his long and eminently useful career as a professor and as a public servant, has assisted at the very beginning of some of the most interesting chapters of applied chemistry, here and abroad.

Some of his pupils have become leaders in chemical industry; others have found in his teachings the very conception of new chemical processes which made their names known throughout the whole world.

Industrial chemistry has been defined as "the chemistry of dollars and cents."

This rather cynical definition, in its narrower interpretation, seems to ignore entirely the far-reaching economic and civilizing influences which have been brought to life through the applications of science; it fails to do justice to the fact that the whole fabric of modern civilization becomes each day more and ever more interwoven with the endless ramifications of applied chemistry.

### Beginning of Chemical Industries in France

The earlier effects of this influence do not date back much beyond one hundred and odd years. They became distinctly evident during the first French Republic, increased under Napoleon, gradually spread to neighboring countries, and then reaching out farther, their influence is now obvious throughout the whole world.

France, during the revolution, scattered to the winds old traditions and conventionalities, in culture as well as in politics. Until then, she had mainly impressed the world by the barbaric, wasteful splendor of her opulent kings, at whose courts the devotees of science received scant attention in comparison to the more ornamental artists and belles-lettrists, who were petted and rewarded alongside of the all-important men of the sword.

In fact, as far as the culture of science was concerned, the Netherlands, Germany and Italy, and more particularly England, were head and shoulders above the France of "le Roi Soleil."

The struggles of the new régime put France in the awkward position of the legendary beaver which "had to climb a tree."

If for no other reason, she needed scientists to help her in her wars against the rulers of other European nations. She needed them just as much for repairing her crippled finances and her badly disturbed industries which were dependent upon natural products imported until then, but of which the supply had suddenly been cut off by the so-called Continental Blockade. Money-prizes and other inducements had been offered for stimulating the development of chemical processes, and —what is more significant—patent laws were promulgated so as to foster invention.

Nicolas Leblanc's method for the manufacture of soda to replace the imported alkalis, Berthollet's method for bleaching with chlorine, the beet-sugar industry, to replace cane sugar imported from the colonies, and several other processes, were proposed.

All these chemical processes found themselves soon lifted from the hands of the secretive alchemist or the timid pharmacist to the rank of real manufacturing methods. Industrial chemistry had begun its lusty career.

First successes stimulated new endeavors and small wonder is it that France, with these favorable conditions at hand, for a while at least, entered into the most glorious period of that part of her history which relates to the development of chemistry, and the arts dependent thereon.

It is difficult to imagine that, at that time, Germany, which now occupies such an enviable position in chemistry, was so far behind that even in 1822, when Liebig wanted to study chemistry at the best schools, he had to leave his own country, and turn to Gay-Lussac, Thénard and Dulong in Paris.

### Development of British Chemical Industry

But the British were not slow to avail themselves of the new opportunities in chemical manufacturing so clearly indicated by the first successes of the French. Their linen bleacheries in Scotland and England soon used an improved method for bleaching with chloride of lime, developed by Tennant, which brought along the manufacture of other chemicals relating thereto, like sulphuric acid and soda.

The chemical reactions involved in all these processes are relatively simple, and after they were once well understood it required mainly resourceful engineering and good commercial abilities to build up successfully the industries based thereon.

From this epoch on dates the beginning of the development of that important industry of heavy chemicals in which the British led the world for almost a century.

In the same way, England had become the leader in another important branch of chemical industry—the manufacture of coal-gas.

### Development of German Chemical Industries

The Germans were soon to make up for lost time. Those same German universities which, when Liebig was a young man, were so poorly equipped for the study of chemistry, were now enthusiastically at work on research along the newer developments of the physical sciences, and before long, the former pupils of France, in their turn, became teachers of the world.

Liebig had inaugurated for the chemical students working under him his system of research laboratories; however modest these laboratories may have been at that time, they carried bodily the study of chemistry from pedagogic boresomeness into a captivating cross-examination of nature.

And it seemed as if nature had been waiting impatiently to impart some of her secrets to the children of men, who for so many generations had tried to settle truth and knowledge by words and oratory and by brilliant displays of metaphysical controversies.

Indeed, at that time, a few kitchen tables, some clumsy glassware, a charcoal furnace or two, some pots and pans, and a modest balance were all that was needed to make nature give her answers.

These modest paraphernalia, eloquent by their very simplicity, brought forth rapidly succeeding discoveries. One of them was truly sensational: Liebig and Wöhler succeeded in accomplishing the direct synthesis of urea; thinking men began to realize the far-reaching import of this revolutionary discovery whereby a purely organic substance had been created in the laboratory by starting exclusively from inorganic materials. This result upset all respected doctrines that organic substances are of a special enigmatic constitution, altogether different from inorganic or mineral compounds, and that they only could be built up by the agency of the so-called "vital force"—whatever that might mean.

---

*An address given at Columbia University to inaugurate the Charles F. Chandler Lectureship. Copyrighted by the Columbia University Press, 1914.

Research in organic chemistry became more and more fascinating; all available organic substances were being investigated one after another by restless experimentalists.

Coal tar, heretofore, a troublesome by-product of gas manufacture, notwithstanding its uninviting, ill-smelling, black sticky appearance, did not escape the general inquisitive tendency; some of its constituents, like benzol or others, were isolated and studied.

Under the brilliant leadership of Kékulé, a successful attempt was made to correlate the rapidly increasing new experimental observations in organic chemistry into a new theory which would try to explain all the numerous facts; a theory which became the sign-post to the roads of further achievements.

### Stimulating Influences of the Dye Industry on Organic Chemistry

The discovery of quickly succeeding processes for making from coal-tar derivatives numerous artificial dyes, rivaling, if not surpassing, the most brilliant colors of nature, made the group of bold investigators still bolder. Research in organic chemistry began to find rapid rewards; entirely new and successful industries based on purely scientific data were springing up in England and France, as well as in Germany.

Some wide-awake leaders of these new enterprises, more particularly in Germany, soon learned that they were never hampered by too much knowledge, but that, on the contrary, they were almost continuously handicapped in their impatient onward march by insufficient knowledge, or by misleading conceptions, if not by incorrect published facts.

This is precisely where the study of organic chemistry received its greaetest stimulating influence and soon put Germany in this branch of science, ahead of all other nations.

Money and effort had to be spent freely for further research. The best scholars in chemistry were called into action. Some men, who were preparing themselves to become professors, were induced to take a leading part as directors in one or another of the new chemical enterprises. Others, who refused to forsake their teachers' career, were retained as advisers or guides, and, in several instances, the honor of being the discoverers of new processes, or a new dye, was made more substantial by financial rewards. The modest German university professor, who heretofore had lived within a rather narrow academic sphere, went through a process of evolution, where the rapidly growing chemical industry made him realize his latent powers and greater importance, and broadened his influence way beyond the confines of his lecture-room. Even if he were altruistic enough to remain indifferent to fame or money, he felt stimulated by the very thought that he was helping, in a direct manner, to build up the nation and the world through the immediate application of the principles of science.

### Industrial Research Laboratories

In the beginning, science did all the giving and chemical industry got most of the rewards; but soon the rôles began to change to the point where frequently they became entirely inverted. The universities did not furnish knowledge fast enough to keep pace with the requirements of the rapidly developing industries. Modern research laboratories were organized by some large chemical factories on a scale never conceived before, with a lavishness which made the best equipped university laboratory appear like a timid attempt. Germany, so long behind France and England, had become the recognized leader in organic manufacturing processes, and developed a new industrial chemistry based more on the thorough knowledge of organic chemistry than on engineering skill.

In this relation, it is worth while to point out that the early organic industrial chemistry, through which Germany was soon to become so important, at first counted its output not in tons, but in pounds—not in size nor in quantity, but in variety and quality.

Now let us see how Germany won her spurs in chemical engineering as well:

At the beginning, the manufacturing problems in organic chemistry involved few, if any, serious engineering difficulties, but required, most of all, a sound theoretical knowledge of the subject; this put a premium on the scientist, and could afford, for a while at least, to ignore the engineer. But when growing developments began to claim the help of good engineers, there was no difficulty whatsoever in supplying them, nor in making them cooperate with the scientists. In fact, since then, Germany has solved, just as successfully, some of the most extraordinary chemical engineering problems ever undertaken, although the development of such processes was entered upon at first from the purely scientific side.

In almost every case, it was only after the underlying scientific facts had been well established, that any attempt was made to develop them commercially.

### Methods of Healthy Development of Scientific Processes

Healthy commercial development of new scientific processes does not build its hope of success upon the cooperation of that class of "promoters" which are always eager to find any available pretext for making "quick money," and whose scientific ignorance contributes conveniently to their comfort by not interfering too much with their self-assurance and their voluble assertions. The history of most of the successful recent chemical processes abounds in examples where, even after the underlying principles were well established, long and costly preparatory team-work had to be undertaken; where foremost scientists, as well as engineers of great ability, had to combine their knowledge, their skill, their perseverence, with the support of large chemical companies, who, in their turn, could rely on the financial backing of strong banking concerns, well advised by tried expert specialists.

History does not record how many processes thus submitted to careful study were rejected because, on close examination, they were found to possess some hopeless shortcomings. In this way, numerous fruitless efforts and financial losses were averted, where less carefully accumulated knowledge might have induced less scrupulous promoters to secure money for plausible but ill-advised enterprises.

In the history of the manufacture of artificial dyes, no chapter gives a more striking instance of long, assiduous and expensive preliminary work of the highest order than the development of the industrial synthesis of indigo. Here was a substance of enormous consumption which, until then, had been obtained from the tropics as a natural product of agriculture.

Professor von Baeyer and his pupils, by long and marvelously clever laboratory work, had succeeded by-and-by in unraveling the chemical constitution of this indigo dye, and had finally indicated some possible methods of synthesis. Notwithstanding all this, it took the Badische Aniline & Soda Fabrik about twenty years of patient research work, carried out by a group of eminent chemists and engineers, before a satisfactory method was devised by which the artificial product could compete in price and in quality with natural indigo.

Germany, with her well-administered and easily enforcible patent laws, has added, through this very agency, a most vital inducement for pioneer work in chemical industries. Who otherwise would dare to take the risk of all the expenses connected with this class of creative work? Moreover, who would be induced to publish the result of his discoveries far and wide throughout the whole world in that steadily flowing stream of patent literature, which, much sooner than any text-books or periodicals, enables one worker to be benefited and to be inspired by the publication of the latest work of others?

### International Scope of Chemical Research

The development of some problems of industrial chemistry has enlisted the brilliant collaboration of men of so many different nationalities that the final success could not, with any measure of justice, be ascribed exclusively to one single race or nation; this is best illustrated by the invention of the different methods for the fixation of nitrogen from the air.

This extraordinary achievement, although scarcely a few years old, seems already an ordinary link in the chain of common, current events of our busy life; and yet, the facts connected with this recent conquest reveal a modern tale of great deeds of the race—an epos of applied science.

Its story began the day when chemistry taught us how indispensable are the nitrogeneous substances for the growth of all living beings.

### Nitrogen Fertilizers

Generally speaking, the most expensive food-stuffs are precisely those which contain most nitrogen; for the simple reason that there is, and always has been, at some time or another, a shortage of nitrogeneous foods in the world. Agriculture furnishes us these proteid- or nitrogen-containing bodies, whether we eat them directly as vegatable products, or indirectly as animals which have assimilated the proteids from plants.

It so happens, however, that, by our ill-balanced methods of agriculture, we take nitrogen from the soil much faster than it is supplied to the soil through natural agencies. We have tried to remedy this discrepancy by enriching the soil with manure or other fertilizers, but this has been found totally insufficient, especially with our methods of intensive culture—our fields want more nitrogen.

So agriculture has been looking anxiously around to find new sources of nitrogen fertilizer. For a short time, an excellent supply was found in the guano deposits of Peru; but this material was used up so eagerly that the supply lasted only a very few years. In the meantime, the ammonium salts recovered from the by-products of the gas-works have come into steady use as nitrogen fertilizer. But, here again, the supply is entirely insufficient, and during the later period our main reliance has been placed on the natural beds of sodium nitrate, which are found in the desert regions of Chile. This has been, of late, our principal source of nitrogen for agriculture, as well as for the many industries which require saltpeter or nitric acid.

In 1898, Sir William Crookes, in his memorable presidential address before the British Association for the Advancement of Science, called our attention to the threatening fact that, at the increasing rate of consumption, the nitrate beds of Chile would be exhausted before the middle of this century. Here was a warning—an alarm call—raised to the human race by one of the deepest scientific thinkers of our generation. It meant no more nor less than that before long our race would be confronted with nitrogen starvation.

In a given country, all other conditions being equal, the abundance or the lack of nitrogen available for nutrition is a paramount factor in the degree of general welfare, or of physical decadence. The less nitrogen there is available as food-stuffs, the nearer the population is to starvation. The great famines in such nitrogen-deficient countries as India and China and Russia are sad examples of nitrogen starvation.

And yet, nitrogen, as such, is so abundant in nature that it constitutes four-fifths of the air we breathe. Every square mile of our atmosphere contains nitrogen enough to satisfy our total present consumption for over half a century. However, this nitrogen is unavailable as long as we do not find means to make it enter into some suitable chemical combination. Moreover, nitrogen was generally considered inactive, and inert, because it does not enter readily in chemical combination.

William Crookes' disquieting message of rapidly approaching nitrogen starvation did not cause much worry to politicians—they seldom look so far ahead into the future. But, to the men of science, it rang like a reproach to the human race. Here, then, we were in possession of an inexhaustible store of nitrogen in the air, and yet, unless we found some practical means for tying some of it into a suitable chemical combination, we should soon be in a position similar to that of a shipwrecked sailor, drifting around on an immense ocean of brine, and yet slowly dying for lack of drinking water.

### Nitric Acid from Air by Means of Electric Discharges

As a guiding beacon, there was, however, that simple experiment, carried out in a little glass tube, as far back as 1785, by both Cavendish and Priestly, which showed that if electric sparks were passed through air, the oxygen thereof was able to burn some of the nitrogen and to engender nitrous vapors.

This seemingly unimportant laboratory curiosity, so long dormant in the text-books, was made a starting point by Charles S. Bradley and D. R. Lovejoy, in Niagara Falls, for creating the first industrial apparatus for converting the nitrogen of the air into nitric acid by means of the electric arc.

As early as 1902, they published their results as well as the details of their apparatus. Although they operated only one full-sized unit, they demonstrated conclusively that nitric acid could thus be produced from the air in unlimited quantities. We shall examine later the reasons why this pioneer enterprise did not prove a commercial success; but to these two American inventors belongs, undoubtedly, the credit of having furnished the first answer to the distress call of Sir William Crookes.

In the meantime many other investigators were at work at the same problem, and soon from Norway's abundant water-falls came the news that Birkeland and Eyde had solved successfully, and on a commercial scale, the same problem by a differently constructed apparatus. The Germans, too, were working on the same subject, and we heard that Schoenherr, also Pauling, had evolved still other methods, all, however, based on the Cavendish-Priestly principle of oxidation of nitrogen. In Norway alone the artificial saltpeter factories use now, day and night, over 200,000 electrical horse-power, which will soon be doubled; while a further addition is contemplated which will bring the volume of electric current consumed to about 500,000 horse-power. The capital invested at present in these works amounts to $27,000,000.

### Cyanamide

Frank and Caro, in Germany, succeeded in creating another profitable industrial process whereby nitrogen could be fixed by carbide of calcium, which converts it into calcium cyanamide, an excellent fertilizer by itself. By the action of steam on cyanamide, ammonia is produced, or it can be made the starting point of the manufacture of cyanides, so profusely used for the treatment of gold and silver ores.

Although the synthetic nitrates have found a field of their own, their utilization for fertilizers is smaller than that of the cyanamide; and the latter industry represents to-day, an investment of about $30,000,000, with three factories in Germany, two in Norway, two in Sweden, one in France, one in Switzerland, two in Italy, one in Austria, one in Japan, one in Canada, but not any in the United States. The total output of cyanamide is valued at $15,000,000 yearly and employs 200,000 horse-power, and preparations are made at almost every existing plant for further extensions. An English company is contemplating the application of 1,000,000 horse-power to the production of cyanamide and its derivatives, 600,000 of which have been secured in Norway and 400,000 in Iceland.

### Nitride Processes

But still other processes are being developed, based on the fact that certain metals or metalloids can absorb nitrogen, and can thus be converted into nitrides; the latter can either be used directly as fertilizers or they can be made to produce ammonia under suitable treatment.

The most important of these nitrade processes seems to be that of Serpek, who, in his experimental factory at Niedermorschweiler, succeeded in obtaining aluminum nitrade in almost theoretical quantities, with the use of an amount of electrical energy eight times less than that needed for the Birkeland-Eyde process and one half less than for the cyanamide process, the results being calculated for equal weights of "fixed" nitrogen.

A French company has taken up the commercial application of this process which can furnish, besides ammonia, pure alumina for the manufacture of aluminum metal.

### Haber's Ammonia Process

An exceptionally ingenious process for the direct synthesis of ammonia, by the direct union of hydrogen with nitrogen, has been developed by Haber in conjunction with the chemists and engineers of the Badische Aniline & Soda Fabrik.

The process has the advantage that it is not, like the other nitrogen-fixation processes, paramountly dependent upon cheap power; for this reason, if for no other, it seems to be destined to a more ready application. The fact that the group of the three German chemical companies which control the process have sold out their former holdings in the Norwegian enterprises to a Norwegian-French group, and are now devoting their energies to the commercial installation of the Haber process, has quite some significance as to expectation for the future.

### The Future of Nitrogen-Fixation Processes

The question naturally arises: Will there be an overproduction and will these different rival processes not kill each other in slaughtering prices beyond remunerative production?

As to over-production, we should bear in mind that nitrogen fertilizers are already used at the rate of about $200,000,000 worth a year, and that any decrease in price, and, more particularly, better education in farming, will probably lead to an enormously increased consumption. It is worth mentioning here that in 1825, the first shipload of Chile saltpeter, which was sent to Europe, could find no buyer, and was finally thrown into the sea as useless material.

Then again, processes for nitric acid and processes for ammonia, instead of interfering, are supplementary to each other, because the world needs ammonia and ammonium salts, as well as nitric acid or nitrates.

It should be pointed out, also, that ultimately, the production of ammonium nitrate may prove the most desirable method so as to minimize freight; for this salt contains much more nitrogen to the ton than is the case with the more bulky calcium-salt, under which form synthetic nitrates are now put into the market.

Before leaving this subject, let us examine why Bradley and Lovejoy's efforts came to a standstill where others succeeded.

First of all, the cost of power at Niagara Falls is three to five times higher than in Norway, and although at the time this was not strictly prohibitive for the manufacture of nitric acid, it was entirely beyond hope for the production of fertilizers. The relatively high cost of power in our country is the reason why the cyanamide enterprise had to locate on the Canadian side of Niagara Falls, and why, up till now, outside of an experimental plant in the South (a 4,000 horse-power installation in North Carolina, using the Pauling process), the whole United States has not a single synthetic nitrogen fertilizer works.

The yields of the Bradley-Lovejoy apparatus were rather good. They succeeded in converting as much as two and one-half per cent of the air, which is somewhat better than their successors are able to accomplish.

But their units, 12 kilowatts, were very much smaller than the 1,000 to 3,000 kilowatts now used in Norway; they were also more delicate to handle, all of which made installation and operation considerably more expensive.

However this was the natural phase through which any pioneer industrial development has to go, and it is more than probable that in the natural order of events, these imperfections would have been eliminated.

But the killing stroke came when financial support was suddenly withdrawn.

### Necessity of Scientific Team-Work and Good Financial Backing

In the successful solution of similar industrial problems, the originators in Europe were not only backed by scientifically well-advised bankers, but they were helped to the rapid solution of all the side problems by a group of specially selected scientific collaborators, as well as by all the resourcefulness of well-established chemical enterprises.

That such conditions are possible in the United States has been demonstrated by the splendid team-work which led to the development of the modern tungsten lamp in the research laboratories of the General Electric Company, and to the development of the Tesla polyphase motor, by the group of engineers of the Westinghouse Company.

True, there are endless subjects of research and development which can be brought to success by the efforts of single independent inventors, but there are some problems of applied science which are so vast, so much surrounded with ramifying difficulties, that no one man, or two men, however exceptional, can either furnish the brains or the money necessary for leading to success within a reasonable time. For such special problems, the rapid cooperation of numerous experts and the financial resources of large establishments are indispensable.

All these examples of the struggle for efficiency and improvement demonstrate why, in industrial chemistry, the question of *dollars and cents* has to be taken very much into consideration.

From this standpoint at least, the "dollars and cents" argument can be interpreted as a symptom of industrial efficiency, and thus, the definition sounds no longer as a reproach. With some allowable degree of accuracy, it formulates one of the economic aspects of any acceptable industrial chemical process.

Indeed, barring special conditions, as, for instance, incompetent or reckless management, unfair competition, monopolies, or other artificial privileges, the money success of a chemical process is the cash plebiscite of approval of the consumers. It is bound, after a time at least, to weed out the inefficient methods.

### Influence of Secondary Factors in Chemical Processes

Some chemists, who have little or no experience with industrial enterprises, are too much over-inclined to judge a chemical process exclusively from the standpoint of the chemical reactions involved therein, without sufficient regard to engineering difficulties, financial requirements, labor problems, market and trade conditions, rapid development of the art involving frequent disturbing improvements in methods and expensive changes in equipment, advantages or disadvantages of the location of the plant, and other conditions so numerous and variable that many of them can hardly be foreseen even by men of experience.

And yet, these seemingly secondary considerations most of the time become the deciding factor of success or failure of an otherwise well-conceived chemical process.

The cost of transportation alone will, frequently, decide whether a certain chemical process is economically possible or not. For instance, the big Washoe Smelter, in Montana, wastes enough sulphuric-dioxide gas to make daily 1,800 tons of sulphuric acid, but that smelter is too far distant from any possible market for such a quantity of otherwise valuable material.

### Natural Deposits of Soda

Another example of the kind is found in the natural deposits of soda or soda lakes in California. One of these soda lakes contains from thirty to forty-two million tons of soda. Here is a natural source of supply which would be ample to satisfy the world's demand for many years to come. Similar deposits exist in other parts of the world, but the cost of transportation to a sufficiently large and profitable market is so exorbitant that, in the meantime, it is cheaper to erect at more convenient points expensive chemical works in which soda is made chemically and from where the market can be supplied more profitably.

In addition, we can cite the artificial nitrate processes in Norway, which, notwithstanding their low efficiency and expensive installation, can furnish nitrate in competition with the natural nitrate beds of Chile, because the latter are hampered by the cost of extraction from the soil where fuel for crystallization is expensive, in addition to the considerable cost of freight.

### Leblanc Soda

But there is no better example illustrating the far-reaching effect of seemingly secondary conditions upon the success of a chemical process than the history of the Leblanc soda process.

This famous process was the forerunner of chemical industry. For almost a century it dominated the enormous group of industries of heavy chemicals, so expressively called by the French "La Grande Industrie Chimique," and now we are witnesses of the lingering death agonies of this chemical colossus. Through the Leblanc process, large fortunes have been made and lost; but even after its death, it will leave a treasure of information to science and chemical engineering, the value of which can hardly be overestimated.

Here, then, is a very well worked-out process admirably studied in all its details,which, in its heroic struggle for existence, has drawn upon every conceivable resources of ingenuity furnished by the most learned chemists and the most skilful engineers, who succeeded in bringing it to an extraordinary degree of perfection, and which, nevertheless, has to succumb before inexorable, although seemingly secondary, conditions.

### Solvay Process

Strange to say, its competitor, the Solvay process, entered into the arena after a succession of failures. When Solvay, as a young man, took up this process, he was, himself, totally ignorant of the fact that no less than about a dozen able chemists had invented and reinvented the very reaction on whicht he had pinned his faith; that, furthermore, some had tried it on a commercial scale, and had, in every instance, encountered failure. At that time, all this must, unodubtedly, have been to young Solvay a revelation sufficient to dishearten almost anybody. But he had one predominant thought to which he clung as a last hope of success, and which would probably have escaped most chemists; he reasoned that, in this process, he starts from two watery solutions, which, when brought together, precipitate a dry product, bicarbonate of soda; in the Leblanc process, the raw materials must be melted together with the use of expensive fuel, after which the mass is dissolved in water, losing all these valuable heat units, while more heat has again to be applied to evaporate to dryness.

After all, most of the weakness of the Leblanc process resides in the greater consumption of fuel. But the cost of fuel, here again, is determined by freight rates. This is so true that we find that the last few Leblanc works which manage to keep alive are exactly those which are situated near unusually favorable shipping points, where they can obtain cheap fuel, as well as cheap raw materials, and whence they can most advantageously reach certain profitable markets.

But another tremendous handicap of the Leblanc process is that it gives as one of its by-products, hydrochloric acid. Profitable use for this acid, as such, can be found only to a limited extent. It is true that hydrochloric acid could be used in much larger quantities for many purposes where sulphuric acid is used now, but it has, against sulphuric acid, a great freight disadvantage. In its commercially available condition, it is an aqueous solution, containing only about one third of real acid, so that the transportation of one ton of acid practically involves the extra cost of freight of about two tons of water. Furthermore, the transportation of hydrochloric acid in anything but glass carboys involves very difficult problems in itself, so that the market for hydrochloric acid remains always within a relatively small zone from its point of production. However, for a while at least, an outlet for this hydrochloric acid was found by converting it into a dry material which can easily be transported; namely, chloride of lime or bleaching-powder.

### Electrolytic Processes a New Competitor

The amount of bleaching-powder consumed in the world practically dictated the limited extent to which the Leblanc process could be profitably worked in competition with the Solvay process. But even this outlet has been blocked during these later years by the advent of the electrolytic alkali processes, which have sprung up successfully in several countries, and which give as a cheap by-product, chlorine, which is directly converted into chloride of lime.

To-day, any process which involves the production of large quantites of hydrochloric acid, beyond what the market can absorb as such, or as derivatives thereof, becomes a positive detriment, and foretells failure of the process. Even if we could afford to lose all the acid, the disposal of large quantities thereof conflicts immediately with laws and ordinances relative to the pollution of the atmosphere or streams, or the rights of neighbors, and occasions expensive damage suits.

Whatever is said about hydrochloric acid applies to some extent to chlorine, produced in the electrolytic manufacture of caustic soda. Here again, the development of the latter industry is limited, primarily, by the amount of chlorine which the market, as such, or as chlorinated products, can absorb.

At any rate, chlorine can be produced so much cheaper by electrolytic caustic alkali processes than formerly, and in the meantime the market price of chloride of lime has already been cut about in half.

In as far as the rather young electrolytic alkali industry has taken a considerable development in the United States, let us examine it somewhat nearer.

At present, the world's production of chloride of lime approximates about half a million tons.

We used to import all our chloride of lime from Europe, until about fifteen years ago, when the first successful electrolytic alkali works were started at Niagara Falls. That ingenious mercury cell of Hamilton Y. Castner—a pupil of Professor Chandler and one of the illustrious sons of the Columbia School of Mines—was first used, and his process still furnishes a large part of all the electrolytic caustic soda and chlorine manufactured here and abroad.

At present, about 30,000 electrical horse-power are employed uninterruptedly for the different processes used in the United States, and our home production has increased to the point where, instead of importing chloride of lime, we shall soon be compelled to export our surplus production.

It looks now as if, for the moment at least, any sudden considerable increase in the production of chloride of lime would lead to over-production until new channels of consumption of chloride of lime or other chlorine products can be found.

However, new uses for chlorine are being found every day. The very fact that commercial hydrochloric acid of exceptional purity is now being manufactured in Niagara Falls by starting from chlorine, indicates clearly that conditions are being reversed; no longer than a few years ago, when chlorine was manufactured exclusively by means of hydrochloric acid, this would have sounded like a paradox.

### Organic Chlorine Products

The consumption of chlorine for the preparation of organic chlorination products utilized in the dye-stuff industry, is also increasing continually, and its use for the manufacture of tetrachloride of carbon and so-called acetylen chlorination products, has reached importance.

There is probably a much overlooked but wider opening for chlorinated solvents in the fact that ethylen-gas can be prepared now at considerably lower cost than acetylen, and that ethylen-chloride, or the old known "Dutch Liquid," is an unusually good solvent. It has, furthermore, the great advantage that its specific gravity is not too high, and its boiling point, too, is about the right temperature. It ought to be possible to make it at such a low price that it would find endless applications where the use of other chlorination solvents has thus far been impossible.

The chlorination of ores for certain metallurgical processes may eventually open a still larger field of consumption for chlorine.

In the meantime, liquified chlorine gas, obtained by great compression, or by intense refrigeration, has become an important article of commerce, which can be transported in strong steel cylinders. Its main utilization resides in the manufacture of tin chloride by the Goldschmidt process for reclaiming tin-scrap. It is finding, also, increased applications as a bleaching agent and for the purification of drinking water, as well as for the manufacture of various chlorination products.

Its great handicap for rapid introduction is again the question of freight, where heavy and expensive containers become indispensable.

In most cases the transportation problem of chlorine is solved more economically by handling it as chloride of lime, which, after all, represents chlorine or oxygen in solid form, easily transportable.

It would seem as if the freight difficulty could easily be eliminated by producing the chlorine right at the spot of consumption. But this is not always so simple as it may appear. To begin with, the cost of an efficient plant for any electrolytic operation is always unusually high as compared to other chemical equipments. Then, also, small electrolytic alkali plants are not profitable to operate. Furthermore, the conditions for producing cheap chlorine depend on many different factors, which all have to coordinate advantageously; for instance, cheap power, cheap fuel and cheap raw materials are essential, while, at the same time, a profitable outlet must be found for the caustic soda.

Lately, there has been a considerable reduction of the market price of caustic soda; all this may have for effect that the less efficient electrolytic processes will gradually be eliminated; although this may not necessarily be the case for smaller plants which do not compete in the open market, but consume their own output for some special purpose.

### Advantages and Disadvantages of Different Types of Electrolytic Alkali Cells

Several distinct types of electrolytic cells are now in successful use, but experience seems to demonstrate that the so-called diaphragm cells are cheapest to construct and to operate, provided, however, no exception be taken to the fact that the caustic soda obtained from diaphragm cells always contains some sodium chloride, usually varying from two or three per cent, which it is not practical to eliminate, but which for almost all purposes does not interfere in the least with its commercial use.

Mercury cells give a much purer caustic soda, and this may, in some cases, compensate for their more expensive equipment and operation. Moreover, there are some purposes where the initial caustic solution of rather high concentration, produced directly in these cells, can be used as it is without further treatment, thus obviating further concentration and cost of fuel.

The expenses for evaporation and elimination of salt from the raw caustic solutions increase to an exaggerated extent with some types of diaphragm cells, which produce only very weak caustic liquors. This is also the case with the so-called "gravity cell," sometimes called the "bell type," or "Aussig type," of cell. But these gravity cells have the merit of dispensing with the delicate and expensive problem of diaphragms. On the other hand, their units are very small, and, on this account, they necessitate a rather complicated installation, occupying an unusually large floor space and expensive buildings.

The general tendency is now toward cells which can be used in very large units, which can be housed economically, and of which the general cost of maintenance and renewal is small; some of the modern types of diaphragm cells are now successfully operating with 3000 to 5000 amperes per cell.

As to the possible future improvements in electrolytic alkali cells, we should mention that in some types the current efficiencies have practically reached their maximum and average ampere efficiencies as high as 95 to 97 per cent have been obtained in continuous practise. The main difficulty is to reinforce these favorable results by the use of lower voltage, without making the units unnecessarily bulky, or expensive in construction, or in maintenance, all factors which soon outweigh any intended saving of electric current.

Here, more than in any other branch of chemical engineering, it is easy enough to determine how "good" a cell is on a limited trial, but it takes expensive, long continuous use on a full commercial scale, running uninterruptedly day and night for years, to find out how "bad" it is for real commercial practise.

### Cheap Power Not the Only Factor

In relation to the electrolytic alkali industry, a great mistake is frequently committed by considering the question of power as paramount; true enough, cheap power is very important, almost essential, but certainly it is not everything. There have been cases where it was found much cheaper in the end to pay almost double for electric current in a certain locality, than in another site not far distant from the first, for the simple reason that the cheaper power supply was hampered by frequent interruptions and expensive disturbances, which more than offset any possible saving in cost of power.

In further corroboration, it is well known that some of the most successful electrolytic soda manufacturers have found it to their advantage to sacrifice power by running their cells at decidedly higher voltage than is strictly necessary—which simply means consuming more power—and this in order to be able to use higher current densities, thereby increasing considerably the output of the same size units, and thus economizing on the general cost of plant operation. Here is one of the ever recurring instances in chemical manufacturing where it becomes more advantageous to sacrifice apparent theoretical efficiency in favor of industrial expediency.

All this does not diminish the fact that the larger electrochemical industries can only thrive where cheap power is available.

### Importance of Cheap Power for Electrochemical Processes

Modern progress of electrical engineering has given us the means to utilize socalled natural powers; until now, however, we have only availed ourselves of the water-power developed from rivers, lakes and waterfalls. As far as large electric power generation is concerned, the use of the wind, or the tide, or the heat of the sun, represents, up till now, nothing much beyond a mere hope of future possibilities.

In the meantime, it so happens, unfortunately, that many of the most abundant water-powers of the world are situated in places of difficult access, far removed from the zone of possible utilization.

But, precisely on this account, it would appear, at first sight, as if the United States, with some of her big water-powers situated nearer to active centers of consumption, would be in an exceptionally favorable condition for the development of electrochemical industries. On closer examination, we find, however, that the cost of water-power, as sold to manufacturers, is, in general, much higher than might be expected; at any rate, it is considerably more expensive than the cost of electric power utilized in the Norway nitrate enterprises.

This is principally due to the fact that in the United States, water-power, before it is utilized by the electrolytic manufacturer, has already to pay one, two and sometimes three, profits, to as many intermediate interests, which act as so many middlemen between the original water-power and the consumer. Only in such instances as in Norway, where the electrochemical enterprise and the development of the water-power are practically in the same hands, can electric current be calculated at its real cheapest cost.

Neither should the fact be overlooked that the best of our water-powers in the east are situated rather far inland. Although this does not matter much for the home market, it puts us at a decided disadvantage for the exportation of manufactured goods, in comparison again with Norway, where the electrolytic plants are situated quite close to a good sea-harbor open in all seasons.

### Increasing Use of Gas Power

Some electrochemical enterprises require cheap fuel just as much as cheap power; and, on this account, it has proved sometimes more advantageous to dispense entirely with water-power by generating gas for fuel as well as for power from cheap coal or still cheaper peat.

At present most of our ways of using coal are still cumbersome and wasteful, although several efficient methods have been developed which some day will probably be used almost exclusively, principally in such places where lower grades of cheap coal are obtainable.

I refer here particularly to the valuable pioneer work of that great industrial chemist, Mond, on cheap water-gas production, by the use of limited amount of air in conjunction with water vapor.

More recently this process has been extended by Caro, Frank and others, to the direct conversion of undried peat into fuel-gas.

By the use of these processes, peat or lower grades of coal, totally unsuitable for other purposes, containing, in some instances, as much as 60 to 70 per cent of incombustible constituents, can be used to good advantage in the production of fuel for power generation.

Whether Mond-gas will ever be found advantageous for distribution to long distances, is questionable, because its heating value per cubic foot is rather less than that of ordinary water-gas, but this does not interfere with its efficient use in internal combustion engines.

In general, our methods for producing or utilizing gas in our cities do scant justice to the extended opportunities indicated by our newer knowledge.

Good fuel-gas could be manufactured and distributed to the individual household consumer at considerably cheaper rates, if it were not for antiquated municipal specifications, which keep on prescribing photometric tests instead of insisting on standards of fuel value, which makes the cost of production unnecessarily high, and disregards the fact that for lighting, the Welsbach mantle has rendered obsolete the use of highly carbureted gas as a bare flame. But for those unfortunate specifications, cheap fuel-gas might be produced at some advantageous central point, where very cheap coal is available; such heating gas could be distributed to every house and every factory, where it could be used cleanly and advantageously, like natural gas, doing away at once with the black coal smoke nuisance, which now practically compels a city like New York to use nothing but the more expensive grades of anthracite coal. It would eliminate, at the same time, all the bother and expense caused through the clumsy and expensive methods of transportation and handling of coal and ashes; it would relieve us from many unnecessary middlemen which now exist between coal and its final consumer.

### New Power Centers to Compete with Water-Power

The newer large-sized internal combustion engines are introducing increasing opportunities for new centers of power production where waste gas or blast-furnaces or coke-ovens, or where deposits of inferior coal or peat, are available.

If such centers are situated near tide-water, this may render them still more advantageous for some electrochemical industries, which, until now, were compelled to locate near some inland water-powers.

Nor should we overlook the fact that the newer methods for the production of cheap fuel-gas offer excellent opportunities for an increased production of valuable tar by-products, and more particularly of ammonium salts; the latter would help to a not inconsiderable extent in furnishing more nitrogen fertilizer.

It is somewhat remarkable that a greater effort has already been made to start the industrial synthesis of nitrogen products than to economize all these hitherto wasted sources of ammonia.

### Our Unbalanced Methods of Agriculture

In fact, science indicates still other ways, somewhat of a more radical nature, for correcting the nitrogen deficiencies in relation to our food supply.

Indeed, if we look at this matter from a much broader standpoint, we may find that, after all, the shortage of nitrogen in the world is attributable to a large extent to our rather one-sided system of agriculture. We do not sufficiently take advantage of the fact that certain plants, for instance those of the group of Leguminosæ, have the valuable property of easily assimilating nitrogen from the air, without the necessity of nitrogen fertilizers.

In this way, therefore, the culture of certain Leguminosæ can insure enough nitrogen for the soil so that, in rotation with nitrogen consuming crops, like wheat, we could dispense with the necessity of supplying any artificial nitrogen fertilizers.

The present nitrogen deficiency is influenced further by two other causes:

The first cause is our unnecessary exaggerated meat diet, in which we try to find our proteid requirements, and which compels us to raise so many cattle, while the amount of land which feeds one head of cattle could furnish, if properly cultivated, abundant vegetable food for a family of five.

The second cause is our insufficient knowledge of the way to grow and prepare for human food just those vegetables which are richest in proteids. Unfortunately, it so happens that exactly such plants as, for instance, the soy-bean are not by any means easily rendered palatable and digestible; while any savage can eat raw meat, or can readily cook, boil or roast it for consumption.

On this subject, we can learn much from some Eastern people, like the Japanese, who have become experts in the art of preparing a variety of agreeable food products from that refractory soy-bean, which contains such an astonishingly large amount of nutritious proteids, and which, long ago, became for Japan a wholesome, staple article of diet.

But on this subject, the Western races have not yet progressed much beyond the point of preparing cattle-feed and paint oil from the soy-bean, although the more extended culture of this, or similar plants, might easily work about a revolution in our agricultural economies.

### Agriculture a Branch of Industrial Chemistry

Agriculture, after all, is nothing but a very important branch of industrial chemistry, although most people seem to ignore the fact that the whole prosperity of agriculture is based on the success of that photochemical reaction which, under the influence of the light of the sun, causes the carbon dioxide of the air to be assilimated by the chlorophyl of the plant.

### Possibilities of Photo-Chemistry

It is not impossible that photochemistry, which hitherto has busied itself almost exclusively within the narrow limits of the art of making photographic images, will, some day, attain a development of usefulness at least as important as all other branches of physical chemistry. In this broader sense photochemistry seems an inviting subject for the agricultural chemist. The possible rewards in store in this almost virgin field may, in their turn, by that effect of superinduction between industry and science, bring about a rapid development similar to what we have witnessed in the advancement of electricity, as well as chemistry, which both began to progress by bounds and leaps, way ahead of other sciences, as soon as their growing industrial applications put a high premium on further research.

Photochemistry may allow us some day to obtain chemical effects hitherto undreamed of. In general, the action of light in chemical reactions seems incomparably less brutal than all means used heretofore in chemistry. This is the probable secret of the subtle chemical syntheses which happen in plant life. To try to duplicate these delicate reactions of nature by our present methods of high temperatures, electrolysis, strong chemicals and other similar torture-processes, seems like trying to imitate a masterpiece of Gounod by exploding a dynamite cartride between the strings of a piano.

### Some Problems for the Future

But there are endless other directions for scientific research, relating to industrial applications, which, until now, do not seem to have received sufficient attention.

For instance, from a chemical standpoint, the richest chemical enterprise of the United States, the petroleum industry, has hitherto chiefly busied itself with a rather primitive treatment of this valuable raw material, and little or no attention has been paid to any methods for transforming at least a part of these hydrocarbons into more ennobled products of commerce than mere fuel or illuminants.

A hint as to the enormous possibilities which may be in store in that direction is suggested by the recent work in Germany and England on synthetic rubber; the only factor which prevents extending the laboratory synthesis of rubber into an immense industrial undertaking is that we have not yet learned how to make cheaply the isoprene or other similar non-saturated hydro-carbons which are the starting point in the process which changes their molecules, by polymerization, into rubber.

Nor has our science begun to find the best uses for such inexpensive and never exhaustible vegetable products as cellulose or starch. Quite true, several important manufacturers, like that of paper nitro-cellulose, glucose, alcohol, vinegar and some others, have been built on it; but to the chemist at least, it seems as if a much greater development is possible in the cheaper and more extended production of artificial fiber. Although we have succeeded in making so-called artificial silk, this article is still very expensive; furthermore, we have not yet produced a cheap, good, artificial fiber of the quality of wool.

If we have made ourselves independent of Chile for our nitrogen supply, we are still absolutely at the mercy of the Stassfurt mines in Germany for our requirements of soluble potash-salts, which are just as necessary for agriculture. Shall we succeed in utilizing some of the proposed methods for converting that abundant supply of feldspar, or other insoluble potash-bearing rocks, into soluble potash-salts by combining the expensive heat treatment with the production of another material like cement, which would render the cost of fuel less exorbitant? Or shall the problem be solved in setting free soluble potassium salts as a by-product in a reaction engendering other staple products consumed in large quantities?

### Our Ignorance Relative to Constitution of the Globe

We have several astonishingly conflicting theories about the constitution of the center of the globe, but we have not yet developed the means to penetrate the world's crust beyond some deep mines—merely an imperceptible faint scratch on the surface—and in the meantime we keep on guessing, while to-day astronomers know already more about the surface of the planet Mars than we know about the interior of the globe on which we live.

Nor have we learned to develop or utilize the tremendous pressures under which most minerals have been formed, and still less do we possess the means to try these pressures, in conjunction with intensely high temperatures.

No end of work is in store for the research chemist, as well as for the chemical engineer, who can think by himself, without always following the beaten track. We are only at the beginning of our successes, and yet, when we stop to look back to see what has been accomplished during the last generations, that big jump from the rule-of-thumb to applied science is nothing short of marvelous.

Whoever is acquainted with the condition of human thought to-day must find it strange, after all, that scarcely seventy years ago, Mayer met with derision even amongst the scientists of the time, when he announced to the world that simple but fundamental principle of the conservation of energy.

We can hardly conceive that just about the time the Columbia School of Mines was founded, Liebig was still ridiculing Pasteur's ideas on the intervention of microorganisms in fermentation, which have proved so fecund in the most epoch-making applications in science, medicine, surgery and sanitation, as well as in many industries.

Fortunately, true science, contrary to other human avocations, recognizes nobody as an "authority," and is willing to change her beliefs as often as better studied facts warrant it; this difference has been the most vital cause of her never ceasing progress.

To the younger generation, surrounded with research laboratories everywhere, it may cause astonishment to learn that scarcely fifty years ago, that great benefactor of humanity, Pasteur, was still repeating his pathetic pleadings with the French government to give him more suitable quarters than a damp, poorly lighted basement, in which he was compelled to carry on his research; and this was, then, the condition of affairs of no less a place than Paris, the same Paris that was spending, just at that time, endless millions for the building of her new Opera-Palace.

### Reason for America's Slow Development of Chemical Industry

Such facts should not be overlooked by those who might think that America has been too slow in fostering chemical research.

If the United States has not participated as early as some European countries in the development of industrial chemistry, this was chiefly because conditions here were so totally different from those of nations like Germany, England and France, that they did not warrant any such premature efforts.

In a country so full of primary resources, agriculture, forests, mines and the more elementary industries directly connected therewith, as well as the problems of transportation, appealed more urgently to American intellectual men of enterprise.

Why should anybody here have tried to introduce new, difficult or risky chemical industries, when on every side more urgently important fields of enterprise were inviting all men of initiative?

Chemical industries develop along the lines furnished by the most immediate needs of a country. Our sulphuric acid industry, which can boast to-day of a yearly production of about three million tons, had to begin in an exceedingly humble way, and the first small amounts of sulphuric acid manufactured here found a very scant outlet.

It required the growth of such fields of application as petroleum refining, superphosphates, explosives and others, before the sulphuric acid industry could grow to what it is to-day.

### Exports and Imports Between the United States and Germany

At present, similar influences are still dominating our chemical industries; they are generally directed to the mass production of partly manufactured articles. This allows us to export, at present, to Germany, chemicals in crude form, but in greater value than the total sum of all the chemical products we are importing from her; although it cannot be denied that a considerable part of our imports are products like alizarine, indigo, aniline dyes and similar synthetic products which require higher chemical manufacturing skill.

In this connection it may be pointed out that our exports of oleomargarine, to Germany alone, are about equivalent to our imports of aniline dyes.

### Some Chemical Industries in Which the United States Was Pioneer

But all this does not alter the fact that in several important chemical industries the United States has been a pioneer. Such flourishing enterprises as that of the artificial abrasives, carborundum and alundum, calcium carbide, aluminum and many others, testify how soon we have learned to avail ourselves of some of our water-power.

One of the most important chemical industries of the world, the sulphite cellulose industry, of which the total annual production amounts to three and a half million tons, was originated and developed by a chemist in Philadelphia, B. C. Tilgman. But its further development was stopped for awhile on account of the same old trouble, lack of funds, after $40,000 were spent, until some years later, it was taken up again in Europe and reintroduced in the United States, where it has developed to an annual production of over a million tons.

What has been accomplished in America in chemical enterprises and what is going on now in industrial research has been brilliantly set forth by Mr. Arthur D. Little.

### Early Beginning of Study of Chemistry in the United States

Nor at any time in the history of the United States was chemistry neglected in this country; this has recently been brought to light in the most convincing manner by Professor Edgar F. Smith, of Philadelphia.

The altruistic fervor of that little group of earlier American chemists, who, in 1792, founded the Chemical Society of Philadelphia (probably the very first chemical society in the world), and in 1811, the Columbia Chemical Society of Philadelphia, is best illustrated by an extract of one of the addresses read at their meeting in 1798:

"The only true basis on which the independence of our country can rest are agriculture and manufactures. To the promotion of these nothing tends in a higher degree than chemistry. It is this science which teaches man how to correct the bad qualities of the land he cultivates by a proper application of the various species of manure, and it is by means of a knowledge of this science that he is enabled to pursue the metals through the various forms they put on in the earth, separate them from substances which render them useless, and at length manufacture them into the various forms for use and ornament in which we see them. If such are the effects of chemistry, how much should the wish for its promotion be excited in the breast of every American! It is to a general diffusion of knowledge of this science, next to the virtue of our countrymen, that we are to look for the firm establishment of our independence. And may your endeavors, gentlemen, in this cause, entitle you to the gratitude of your fellow-citizens."

This early scientific spirit has been kept alive throughout the following century by such American chemists as Robert Hare, E. N. Horsford, Wolcott Gibbs, Sterry Hunt, Lawrence Smith, Carey Lea, Josiah P. Cooke, John W. Draper, Willard Gibbs and many others still living.

Present conditions in America can be measured by the fact that the American Chemical Society alone has over seven thousand members, and the Chemists' Club of New York has more than a thousand members, without counting the more specialized chemical organizations, equally active, like the American Institute of Chemical Engineers, the American Electrochemical Society and many others.

During the later years chemical research is going on with increasing vigor, more especially in relation to chemical problems presented by enterprises which at first sight seem rather remote from the so-called chemical industry.

### Research in America

But the most striking symptom of newer times is that some wealthy men of America are rivaling each other in the endowment of scientific research on a scale never undertaken before, and that the scientific departments of our government are enlarging their scope of usefulness at a rapid rate.

But we are merely at the threshold of that new era where we shall learn better to use exact knowledge and efficiency to bring greater happiness and broader opportunities to all.

However imposing may appear the institutions founded by the Nobels, the Solvays, the Monds, the Carnegies, the Rockefellers and others, each of them is only a puny effort to what is bound to come when governments will do their full share. Fancy that if, for instance, the Rockefeller Institute is spending to good advantage about half a million dollars per annum for medical research, the chewing-gum bill of the United States alone would easily support half a dozen Rockefeller Institutes; and what a mere insignificant little trickle all these research funds amount to, if we have the courage to compare them to that powerful gushing stream of money which yearly drains the war budget of all nations.

In the meantime the man of science is patient and continues his work steadily, if somewhat slowly, with the mean hitherto at his disposal. His patience is inspired by the thought that he is not working for to-day, but for to-morrow. He is well aware that he is still surrounded by too many "men of yesterday," who delay the results of his work.

### Efficiency vs. Waste

Sometimes, however, he may feel discouraged that the very efficiency he has succeeded in reaching at the cost of so many painstaking efforts, in the economical production of such an article of endlessly possible uses, as Portland cement, is hopelessly lost many times over and over again, by the inefficiency, waste and graft of middlemen and political contractors, by the time it gets on our public roads, or in our public buildings. Sometimes the chaos of ignorant brutal waste which surrounds him everywhere may try his patience. Then, again, he has a vision that he is planting a tree which will blossom for his children and will bear fruit for his grandchildren.

### New Type of Man Evolved by Scientific Education

In the meantime, industrial chemistry, like all other applications of science, has gradually called into the world an increasing number of men of newer tendencies, men who bear in mind the future rather than the past, who have acquired the habit of thinking by well-established facts, instead of by words, of aiming at efficiency instead of striking haphazard at ill-defined purposes. Our various engineering schools, our universities, are turning them out in ever-increasing numbers, and better and better prepared for their work. Their very training has fitted them out to become the most broad-minded progressive citizens.

However, their sphere of action, until now, seldom goes beyond that of private technical enterprises for private gain. And yet, there is not a chemist, not an engineer, worthy of the name, who would not prefer efficient, honorable public service, freed from party politics, to a mere money-making job.

### Government by Engineers or by Lawyer-Politicians?

But most governments of the world have been run for so long almost exclusively by lawyer-politicians, that we have come to consider this as an unavoidable evil, until sometimes a large experiment of government by engineers, like the Panama Canal, opens our eyes to the fact that, after all, successful government is—first and last—a matter of efficiency, according to the principles of applied science.

Was it not one of our very earliest American chemists, Benjamin Thompson, of Massachusetts, later knighted in Europe as Count Rumford, who put in shape the rather entangled administration of Bavaria by introducing scientific methods of government?

Pasteur was right when one day exasperated by the politicians who were running his beloved France to ruin, he exclaimed:

"In our century science is the soul of prosperity of nations and the living source of all progress. Undoubtedly the tiring daily discussions of politics seem to be our guide. Empty appearances! What really leads us forward are a few scientific discoveries and their applications."

---

The British Guiana gold industry has experienced a revival in the last two years, according to a consular report by Lester W. Collins. The recovery is mainly by dredging and hydraulicking. Lode mining has been disappointing. In spite of the crude methods employed, the output for 1913 was 51,765 oz.

# Cyanide Practice in the Porcupine District, Ontario, Canada—I.

BY H. C. PARMELEE

### General

About 100 miles northwest of Cobalt in northern Ontario lies the gold-mining district of Porcupine. A slight divide between the Cobalt and Porcupine districts separates the St. Lawrence and Hudson Bay watersheds, Porcupine being on the northerly or Hudson Bay slope. Gold mining has attracted attention to the Porcupine area for the last four or five years, following the spectacular discovery on what is now the Dome property. In 1911 the district was ravaged by a succession of forest fires which destroyed the mine and mill buildings of the Hollinger, Dome and other companies, and wiped out the town of South Porcupine; but despite these obstacles the district is now in a prosperous condition and is beginning to make a substantial gold production.

According to statistics compiled by Mr. A. A. Cole, mining engineer for the Temiskaming & Northern Ontario Railway Commission, the gold production of the Porcupine district in 1913 was valued at $4,284,928, which nearly equals the entire previous production of Ontario. The output of gold for 1913 increased 147 per cent over that of 1912, and constituted 29 per cent of the gold production of Canada and 95 per cent of that of Ontario.

FIG. 1—HOLLINGER MILL, TIMMINS, PORCUPINE DISTRICT

In marked contrast to the complex silver ores of Cobalt, those of Porcupine consist mainly of free gold in quartz and schist, accompanied by varying small quantities of sulphide minerals, principally pyrite. Metallurgy at Porcupine is accordingly much simpler than at Cobalt, and a high recovery is easily made by amalgamation and cyanidation. Nevertheless milling practice in the Porcupine district is diverse, and of the four principal mills each differs decidedly from the others in equipment and method of operation.

### The Hollinger Mill

The largest and most important producing company in the Porcupine district is the Hollinger Gold Mines, Ltd. The first mill erected by the company was destroyed by fire in May, 1911, and was immediately replaced by the present plant, which commenced operating in June, 1912, and has been in successful operation since that time. The milling record for 1913 shows a total of 140,131 tons of ore treated, of which 138,291 tons was from the Hollinger mine, having an average value of $18.56 per ton. The extraction was 96.1 per cent, and the cost of milling was $1.63 per ton.

The process adopted at the Hollinger consists, briefly, in crushing and grinding the ore in cyanide solution by means of stamps and tube mills, concentrating, and separately cyaniding the concentrate and tailing. The concentrate is finely washed and dewatered in a Door three-deck washing classifier, and the tailing is treated by continuous decantation and vacuum filtration. The Merrill system of zinc-dust precipitation is used, and the precipitate is smelted and refined.

### Nature and Value of the Ore

As delivered to the mill, Hollinger ore is composed of about one-fourth quartz and three-fourths schist, the latter being quite heavily mineralized with pyrite which constitutes about 5 per cent of the mill feed. Gold occurs throughout the ore in the free state and is very finely divided. It is accompanied also by some silver, the native metal having a gold fineness of 825 and a silver fineness of 125. The gross value of the ore now being treated is between $13 and $14 per ton, which is less than the average value for 1913, due to the development of large lower-grade ore bodies in the mine.

The ore is raised from the mine in 3-ton skips and delivered to the coarse-breaking plant where it is crushed successively through No. 7½ and No. 5 gyratories. A trommel screen with 2½-in. openings intervenes between the two crushers and removes the undersize from the discharge of the first gyratory. An extra man is employed on the second crusher to remove wood and steel from the ore. He takes out about 1 cu. ft. of wood per hour and more or less steel, thus reducing the possibility of breakage at the crusher and improving the mill work generally. The expense of $2.25 per day is fully justified by the results obtained.

The crushed ore is conveyed to the top of the mill by an inclined belt conveyor, 350 ft. long. The inclination is 12 deg. and the rate of travel is 250 ft. per minute. This belt has been in service for two years and has an anticipated life of two and a half years. A Merrick automatic weigher is to be installed on the belt to give an accurate record of ore delivered to the mill. A further change under consideration is to screen the ore before delivery to the battery bins, and install additional tube mills to grind the fine portion.

The battery bins have a capacity of 1000 tons. They are flat-bottomed, and the ore is discharged to the batteries through side gates. This arrangement necessitates occasional shoveling when ore is low in the bins, and it is likely that a change will be made, substituting central hoppers for the flat bottom. In that event the batteries will be equipped with belt feeders operated by Hooper attachments to the tappets.

At present the crushing equipment consists of forty 1500-lb. stamps, but the mill capacity is being increased by the addition of twenty more. They drop 6¼ in., 108 times a minute, being run rapidly in order to secure a good splash in the mortars. The height of discharge is 2 in. The screens have oblong openings—four meshes per inch in one direction and three in the other. The wires forming the warp are of lighter weight than the shoot wires, giving a screen that does not blind as easily as one in which all wires are of the same weight.

### Maple-Cog Bevel-Gears on Stamp Drive

The stamps are grouped in batteries of ten, with separate 6½-in. cam shafts for each set of five stamps. A 100-hp motor provides the power ten stamps and one tube mill, a countershaft for the batteries being driven from the tube mill shaft by maple-cog bevel-gears. The substitution of maple-cog gears for steel has effected a great saving in cost. Steel gears cost $105 per set and lasted five months, whereas a set of maple cogs costs but $25 and lasts six months. Moreover, the maple-cog gears are practically silent in operation, while the steel gears were very noisy. The motors have Reynolds silent-chain drives, but these will be replaced by Wuest gears, which are expected to prove more satisfactory in transmission of power.

### Stamping in Cyanide Solution

The ore is crushed in cyanide solution added at the batteries at the rate of 3 tons per ton of ore. Under the conditions prescribed the batteries are showing an actual duty of 15 tons per stamp, being in operation 95 per cent of the possible running time. The battery discharge flows to the tube mill-classifier circuit for fine grinding, one tube mill and one Dorr duplex classifier receiving the product from ten stamps. The ratio of stamps to tube mills, 10 to 1, is the same as adopted at the Nipissing mill in Cobalt and is also in accord with the latest South African practice. The ratio of solution to ore, however, 3 to 1, may be considered low. The classifiers are 24 ft. long, being 8 ft. longer than standard machines, and are set at a pitch of 2⅝ in. per foot, thus securing gravity flow to and from tube mills.

Experiment is being made with the Globe tube mill liner, which is a sectional chilled-iron liner resembling the El Oro except that the ribs extend around the inner surface of the tube instead of lengthwise, the space between ribs tapering counter to the travel of the mill. Pebbles become firmly wedged in the space between the ribs and relieve the metal from most of the wear. While the Globe liner has not been in use long enough to determine its life, from present indications it is expected to last more than a year and reduce the cost of tube milling. At present a silex lining 5 in. thick costs $450 in place and lasts about seven months. The time lost in lining with silex is sixty hours. The Globe lining, on the other hand, costs $750 in place, but it probably will last longer than silex, and the time lost in replacing it is only eighteen hours.

Danish and French pebbles are used, at a cost of $20 and $18 per ton, respectively. The consumption of either kind is 4½ lb. per ton of ore treated.

From 75 per cent to 80 per cent of the ore is ground to minus 200-mesh in order to insure liberation and rapid dissolution of the gold. In Table I is given a screen analysis and assay value of the battery and tube mill discharges and both products of the Dorr classifier. A marked concentration will be noted in the tube mill-classifier circuit.

Table I.

| Screen analysis .. | +8 | +20 | +40 | +100 | +150 | +200 | −200 | |
|---|---|---|---|---|---|---|---|---|
| Battery discharge | 17.1 | 31.3 | 14.6 | 17.0 | 3.5 | 1.0 | 15.5 | |

### Rapid Dissolution of Gold in Tube Mills

About 70 per cent of the gold in the ore goes into solution in the tube mills, where cyanide is added to bring the solution up to a strength of 1.3 lb. KCN. A further 26 per cent is dissolved in the subsequent milling operations. Table II shows the distribution of the gold value in a ton of ore at the successive stages of the process, and the progressively diminishing value of the ore from beginning to end of treatment. Table concentrate is cyanided separately from the balance of the ore, and at the time of making the tests on which this table is based, treated concentrate was being returned to the table tailing and receiving the regular cyanide treatment. The item of $0.22 in the table represents this latter part of the concentrate.

Table II.
*Gold Distribution per Ton of Ore*

| | Contained in Concentrate | | Contained in Non-concentrate | | Total | | |
|---|---|---|---|---|---|---|---|
| Treatment | Head | Tailing | Head | Tailing | Head | Tailing | Per Cent Recovery |
| Tube milling. | $10.92 | $3.00 | $2.20 | $0.60 | $13.12 | $3.60 | 72.6 |

| Filtration.... | 0.32 | 0.19 | 0.45 | 0.33 | 0.77 | 0.52 | 1.9 |

### Removal of Wood Pulp at Classifiers

Although a great deal of wood is removed from the ore at the crushers, small pieces find their way to the stamps and are crushed to a coarse pulp. This accumulates in the Dorr classifiers and is removed in a novel manner. As the slime leaves the classifier it flows onto a horizontal screen which retains the small pieces of wood, and these are removed from the screen by a reciprocating brush connected to the classifier mechanism. On the forward stroke of the rakes the brush travels clear of the screen, but is in contact with it on the backward stroke.

A mine-car full of this wood pulp is thus collected every day. It has a value of about $2 per ton. It is burned, and the ash, which has a value of $50 per ton, is added to the concentrate and cyanided. An interesting fact observed in connection with the wood pulp is that only sulphide minerals adhere to it and give it its value. As the wood is of the resinous variety and odorous of the characteristic oils of pine and spruce, it is possible that we have here conditions favorable to the selection of sulphide particles from the slime pulp, according to the principles underlying the process of oil-flotation.

### Changes in Flow-Sheet

Reference is here made to the flow-sheets outlined in Figs. 2 and 3, showing certain important changes that recently have been made in the treatment. Fig. 2 gives the general outline of the method in use prior to June, 1914, and Fig. 3 embodies the subsequent changes which will be mentioned in greater detail later. The main points of difference in the method now adopted are (1) the substitution of primary Dorr thickeners for the dewatering boxes ahead of concentration; (2) the precipitation of solution overflowing these primary thickeners, and (3) the separate treatment of concentrate and tailing.

Another change in operation that has resulted in substantial economy is in the solution circuit. Formerly all of the mill solution was pumped to storage tanks at the top of the mill and then piped back to various points of application. Also, dependence was placed entirely on the shiftmen to regulate the flow of solution. According to the rearranged circuit only a part of the solution is pumped to the head of the mill, and the flow is governed by automatic floats in storage tanks. The change has greatly diminished the power consumed in pumping and has reduced the number of pumps formerly required. The tabulation below gives some comparative data on the two methods of operation.

| | Foot-tons Solution Pumped, 24 Hours | Foot tons Solution Pumped per Ton Ore | Theoretical HP. Required |
|---|---|---|---|
| Former system ..... | 276,480 | 576 | 11.61 |
| Present system...... | 150,840 | 311 | 6.28 |

### Separate Treatment of Mineral and Gangue

A feature of Hollinger practice that is not adopted in the other mills of the district is concentration, with separate cyanidation of concentrate and tailing. The reasons for this will be mentioned later.

Slime from the Dorr classifiers is distributed to ten primary Dorr thickeners, 13 ft. by 6 ft., which dewater the pulp for concentration. The overflow carries off the lighter solids, amounting to about one-quarter of the tonnage, which goes to a 30-ft. by 10-ft. Dorr thickener, the overflow from which passes through Merrill clarifying presses and thence to precipitation. The underflow from this large thickener is added to the table tailing.

The thickened underflow from the primary thickeners contains about 50 per cent solution, but is diluted to 66 2/3 per cent by addition of solution from the second step of continuous decantation before distribution to the Deister concentrating tables. The wash water used in concentration is overflow solution from the thickeners in the second step of continuous decantation. It is applied at the rate of one ton for each ton of solids concentrated. The table tailing thus diluted is pumped to the first step of continuous decantation, while the concentrate is treated separately. Lime is not added to the ore until after concentration.

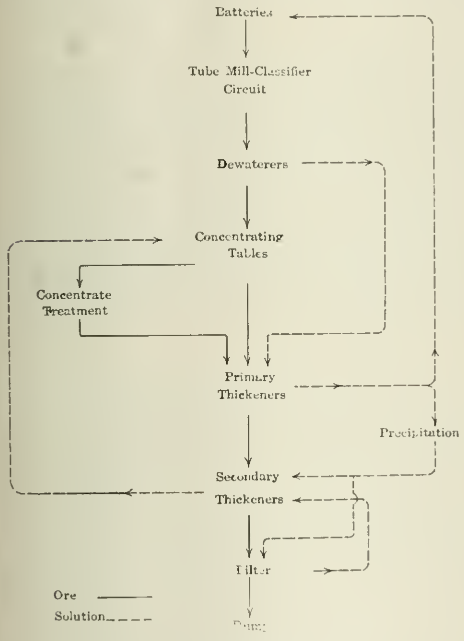

FIG. 2—DIAGRAM OF FORMER METHOD OF TREATMENT, HOLLINGER MILL

## Cyaniding Concentrate

One of the important changes recently made in the mill practice is in the treatment of concentrate. Formerly this product was reground and treated by pan amalgamation, after which the pulp was again combined with the tailing from concentration and put through the cyanide process as outlined in Fig. 2. Recovery by amalgamation proved to be almost nothing and this step was abandoned. Further, the cyanide extraction on concentrate was not as complete as on tailing; and yet after the two had been combined it was impossible either to give the concentrate a special treatment or recover it separately from the tailing for further treatment. Consequently the system was changed as indicated in Fig. 3, and concentrate is now kept entirely separate from tailing. An incidental benefit of this change was an improvement in the work of the thickeners and filters, where the heavy sulphides formerly caused trouble.

The value of the concentrate is about $70 per ton. It is agitated for eight hours in 10-lb. cyanide solution, after which it is washed free from dissolved gold by passing through a Dorr three-deck washing classifier. The residue still has a value of about $6 per ton, but it is impossible to get a further extraction by cyaniding. Experiments indicate that by roasting and then cyaniding an additional extraction can be made and the residue reduced to a value of $1 per ton. Anticipating future treatment by this method, the concentrate residue is being stored.

No particular difficulty is experienced in cyaniding concentrate. No advantage is gained by regrinding, and the solution does not become foul when the concentrate is fresh. Chemical consumption per ton of concentrate treated is as follows: cyanide, 2 lb.; lime, 1 lb. Protective alkalinity is maintained at 1 lb. per ton.

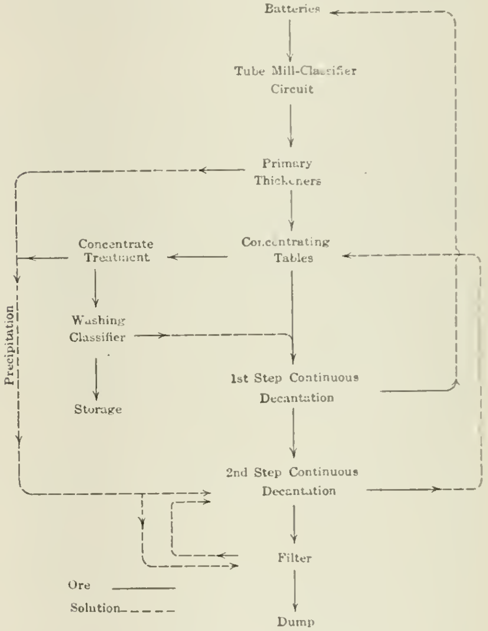

FIG. 3—DIAGRAM OF PRESENT METHOD OF TREATMENT, HOLLINGER MILL

Agitation is performed by mechanically stirring a pulp of 40 per cent solids and 60 per cent solution in Wheeler grinding pans. Aeration and thorough mixing are aided by pockets riveted to the periphery, opening in the opposite direction to the travel of the stirrers. These pockets have the effect of preventing the continuous swirl of the pulp by breaking the waves formed by the stirrers and producing counter currents. The device is very successful and well adapted to use with mechanical stirrers.

## Continuous Decantation of Slime Tailing

Although a Moore vacuum filter is used for final dewatering and washing of slime, continuous decantation is relied upon for the displacement of most of the dissolved gold before the pulp is filtered. As an example of the tremendous change brought about by the adoption of the decantation process, it may be stated that before it was introduced the filters were daily receiving solution valued at about $7,000, whereas after continuous decantation was adopted only $600 in dissolved gold was sent daily to the filters. This illustrates the value of continuous decantation, even in those cases where a filter is used as a final slime dewaterer.

The equipment for continuous decantation consists of four 30-ft. by 15-ft. Dorr thickeners in the first step, and four 30-ft. by 12-ft. in the second step. The first four thickeners receive the diluted table tailing, combined with wash solution from the concentrate-dewatering classifier. The overflowing solution runs by gravity back to the batteries. The thickened underflow is transferred to the second set of four thickeners and there diluted with barren solution from the precipitation presses and wash solution from the filters. The overflow from the second set of thickeners is used as wash water on the concentrating tables and the thickened underflow is filtered.

### Overload Indicator for Thickeners

All of the Dorr thickeners used in continuous decantation are run at the rate of one revolution in five minutes. Power consumption is about $\frac{1}{8}$ hp for each thickener. Unless these machines are provided with some sort of overload alarm or indicator, thick pulp may be allowed to accumulate abnormally in the bottom of the tank due to variations in amount of feed. The condition may be corrected, of course, by changing the espigot in the discharge pipe, or, where diaphragm pumps are used, increasing their speed or lengthening their stroke. But if the attendant has no warning of the increasing density of the pulp in the bottom of the tank, the vertical shaft may be twisted or the rakes broken before he can relieve the condition by increasing the underflow. Hence the value of an alarm or indicator.

The manufacturers of the Dorr thickener supply an electric overload alarm, in which the increasing resistance of the pulp on the rakes finally causes an electrical contact to be made by the thrust of the driving shaft against a steel spring. The contact rings a bell and indicates on an annunciator the particular thickener involved. An automatic pressure record is also made at the thickener by a pointer that is deflected across a dial by the thrust of the driving shaft. A pencil carried on the end of the pointer registers the maximum pressure on a card placed in the dial.

The indicator adopted by Mr. Cunningham, superintendent of the Hollinger mill, works on a similar principle but has no electrical connections. The thrust of the driving shaft against a light spring is communicated to a pointer that moves across a dial marked with a scale indicating the hp consumed in driving the rakes. The end of the pointer carries a knife-edge extending through a piece of tracing cloth mounted on the dial. As the required power increases, the knife cuts a longer slit through the cloth and thus records the maximum power used at any time during a shift.

As stated before, the power normally required in operating a thickener is about $\frac{1}{8}$ hp. One and two-thirds horse-power will twist the vertical shaft at one-fifth r.p.m. Hence it is desirable that the power applied through the shaft shall not exceed 1/3 hp; and the shiftman is supposed to see that this figure is not exceeded and preferably not reached. The first duty of the attendant coming on shift is to inspect the indicators and report instances of excessive power as indicated by the slit in the tracing cloth. Prompt attention to this duty relieves him of responsibility for the negligence of the shiftman preceding him, while failure to make an immediate inspection and report makes it impossible to throw the blame on his predecessor and leaves him liable for the improper operation of the thickener. This system has resulted in careful attention to the work. The value of the indicators is shown by the fact that no breakage has occurred on those thickeners that are equipped with them, while several instances of damage occurred where they were not installed.

### Vacuum Filtration

The underflow from the last thickeners in the continuous decantation system contains about 35 per cent moisture. It is drawn from the tanks by diaphragm pumps and discharged to the loading tanks of the Moore filter. The pumps are run from $2\frac{1}{2}$-in. eccentrics at a rate of 30 strokes per minute, the eccentric motion being transmitted to the diaphragm by bell cranks. The length of stroke of the diaphragm may be regulated while the pump is running, and is variable between zero and 4 in.

The Moore vacuum filter is arranged in two units, each consisting of two 56-leaf baskets and three tanks for loading, washing and discharging, respectively. A common acid tank serves both units. The baskets are handled by an electric crane of 30 ft. span and have an aggregate filter surface of about 19,000 sq. ft.

The filter leaves are constructed of $\frac{3}{4}$-in. pipe covered with 8-oz. duck. There are two thicknesses of duck about the pipe, four at the corners of the leaf and six at the outside seams. Thus constructed the leaves last 18 months. They are made at the mill at a cost of $12.50 each, of which $7 is for material other than pipe, $3.50 for labor, $1 for assembling and $1 for header and pipe.

Acid treatment is given every five weeks with a 1 per cent commercial hydrochloric acid solution. After three weeks' use of a fresh leaf, however, it is noted that the displacement of gold solution is less efficient and the value of the residue begins to rise. It is likely that acid treatment every three weeks would give better metallurgical results and be more profitable.

A complete cycle of filtration requires 15 minutes for loading, 50 minutes for displacement with barren solution and 15 to 20 minutes for washing with water. A load of 20 tons can be accumulated in 10 minutes, but 15 minutes is the average maintained over long periods of time. The washed cake is discharged with 25 per cent moisture. It has a gross value of $0.55 per ton, the loss in dissolved gold and silver being $0.05 per ton.

The slime in the loading tanks is kept in suspension by agitating with air-lifts, one of which is placed in the center of each hopper. The lift-pipe is 6 in. in diameter and extends to within 6 in. of the bottom of the hopper. A $\frac{3}{4}$-in. air-pipe extends to within 4 in. of the bottom of the lift-pipe, being suspended loosely and connected by hose with a source of compressed air. As the air-pipe opens downward it does not become clogged with slime. Other means of keeping the slime in suspension in these tanks have proved inadequate, but the present method is successful.

### Zinc-Dust Precipitation

Pregnant solution from the overflow of the primary thickeners (Fig. 3) is first partly clarified in a Dorr thickener, as already explained, and finally in two 20-leaf, 36-in. Merrill clarifying presses. These are sluiced three times a shift with a solution at 70 lb. pressure, and acid-treated every three weeks, 800 lb. commercial hydrochloric acid being neutralized in the latter operation. The equipment for precipitation consists of a zinc-dust feeder, three 20-leaf, 52-in. Merrill presses and the necessary complement of pumping apparatus.

The value of pregnant solution is about $5 per ton. The precipitation ratio—tons of solution precipitated per ton of ore—is 2.67, which is low considering the grade of ore treated. Zinc consumption is 0.6 lb. per ton of ore. Chemical consumption of cyanide is 0.2 lb. and mechanical loss 0.25 lb., giving a total of 0.45 lb. per ton of ore. Lime consumption is 2.5 lb. per ton of ore treated.

### Precipitate Smelted in Blast Furnace

Precipitate from the presses is dumped into hoppers underneath, and taken thence by cars to the refinery. Here a smelting mixture is made, thoroughly mixed and allowed to "set," after which it is cut into bricks and smelted in a small blast furnace with 1½ tons of coke per ton of charge. The smelting mixture consists of 100 parts precipitate, 135 litharge, 15 borax, 5 soda ash, 4 sand and some flue dust.

Since the precipitate receives no preliminary acid treatment, the furnace slags have a high zinc content. The precipitate has a value of about $40 per pound and contains 54 per cent zinc and 5 per cent lead, the latter being derived from the lead acetate used in concentrate treatment and from the zinc dust which contains about 2 per cent lead. The slag formed in the first smelt is retreated in the furnace, after which it is sent to the mill and cyanided, an extraction of 60 per cent being made. Flue dust is formed at the rate of 60 lb. per ton of precipitate charge, or about 200 lb. monthly. The following tabulation gives the value of the various products and an average analysis for zinc and lead.

| Product | Gold and Silver, Value per Lb. | Zinc, Per Cent | Lead, Per Cent |
|---|---|---|---|
| Precipitate | $40.00 | 54 | 5 |
| First slag | 0.04 | 35 | 5 |
| Second slag | 0.02 | 28 | 4 |
| Flue dust | 0.50 | 30 | 70 |

The base bullion is cupelled in an English cupel furnace. A cupel mixture that has proved very satisfactory, giving cupels that last for three runs, has the following composition: 100 parts fireclay, 150 cement, and 200 of screened limestone—10 + 60 mesh in size. The cupelled bullion is finally melted and refined in a Monarch oil-fired furnace and cast into bars. The resulting bullion has a total fineness of 960, of which 830 is gold and 130 silver. It contains also about 3 per cent copper and some lead and zinc.

### Cost of Milling

The cost of milling operations for the year 1913 was $1.628 per ton, but this figure is abnormally high owing to irregular and inefficient operation during the early months of the year when there were serious labor disturbances in the district. Current milling cost will vary from $1.10 to $1.15 per ton, and is fairly represented in the distribution given below which is based on the treatment of approximately 15,200 tons of ore during the four-week period ending May 20, 1914. The mill was in operation 94 per cent of the possible running time. The gross value of the ore treated was $12.93 per ton, and the extraction was 95.7 per cent.

### Distribution of Cost

| Account | Per Ton |
|---|---|
| General milling charges | $0.045 |
| Superintendence | .049 |
| Tailing disposal | .017 |
| Heating | .027 |
| Lighting | .006 |
| Shoveling in bins | .004 |
| Assaying | .013 |
| Coarse crushing | .073 |
| Conveying (including amortization of belt) | .033 |
| Stamping | .137 |
| Classifying and tube milling (including 2 new liners) | .196 |
| Concentrating | .050 |
| Handling concentrate | .012 |
| Treating concentrate | .031 |
| Handling pulp | .033 |
| Thickening | .014 |
| Continuous decantation | .036 |
| Filtration | .081 |
| Neutralizing | .018 |
| Clarifying and precipitating | .057 |
| Smelting and refining | .058 |
| Pumping solutions | .022 |
| Cyanide | .074 |
| Cleaning mill | .028 |
| Alterations | .031 |
| Total | $1.145 |

The total working cost for the period above mentioned, including mining, milling, taxes, insurance, employees' loyal service bonus, etc., was $4.219 per ton.

We are indebted to Mr. Noel Cunningham, superintendent of the Hollinger mill for his courtesy in supplying many details and data of operation published in this article.

## A New Theory of the Ammonia Soda Process

BY WILLIAM MASON

The ammonical sodium chloride solution of the ammonia soda process, as carried on at present by the Solvay system, is carbonated in two stages. In the first stage it is treated with carbonic acid until about 80 per cent of the ammonia is carbonated to ammonium carbonate. In the second stage this solution if further treated with carbonic acid and sometime before the whole of the ammonia is converted into ammonium carbonate a precipitate is formed which the author finds is sodium carbonate, and is of opinion that when the whole of the ammonia becomes carbonated a reaction takes place according to the following equation:

$$(NH_4)_2CO_3 + 2NaCl = Na_2CO_3 + 2NH_4Cl.$$

Some of the sodium carbonate is precipitated in such a concentrated solution, while the remainder remains in solution and is precipitated out as sodium bicarbonate in the second stage of carbonation. In Table I are given the results of the working from a Solvay tower which clearly show that this is so, as regularly as from a solution of sodium carbonate.

TABLE I

| Height in Meters | Alkalinity cc n/10 acid to neutralize 10 cc of liquor | Temperature °C | Sodium Chloride grams per 100 cc |
|---|---|---|---|
| 18 | 41.4 | 39.6 | 24.37 |
| 17 | 40.3 | 42.3 | 23.55 |
| 16 | 38.5 | 43.7 | 22.22 |
| 15 | 35.8 | 45.0 | 20.88 |
| 14 | 33.7 | 48.0 | 19.57 |
| 13 | 31.2 | 47.5 | 18.40 |
| 12 | 28.5 | 47.5 | 17.30 |
| 11 | 26.6 | 47.3 | 16.25 |
| 10 | 24.4 | 47.0 | 15.30 |
| 9 | 22.8 | 47.0 | 14.25 |
| 8 | 21.0 | 46.2 | 13.16 |
| 7 | 19.1 | 44.2 | 12.26 |
| 6 | 17.3 | 43.0 | 11.36 |
| 5 | 15.9 | 41.5 | 10.54 |
| 4 | 15.0 | 38.0 | 9.78 |
| 3 | 13.4 | 34.0 | 9.10 |
| 2 | 12.2 | 32.0 | 8.46 |
| 1 | 11.2 | 32.0 | 8.46 |

When the precipitate begins to form, analysis shows that 50 per cent of the sodium chloride has already been decomposed and that there is 11.87 per cent of sodium carbonate in solution. A solution from the center of a Solvay tower contains about 5.83 per cent of sodium carbonate. The mother-liquor, after the separation of the sodium bicarbonate, contains only 0.53 per cent of the same. The following is an analysis of this liquor; grams per 100 c.c.

| | |
|---|---|
| Ammonium carbonate | 8.13 per cent |
| Sodium carbonate | 0.53 per cent |
| Ammonium chloride | 18.13 per cent |
| Sodium chloride | 8.46 per cent |

Analyses of the sodium bicarbonate produced by the Solvay system show that it also contains sodium carbonate:

| | |
|---|---|
| Sodium bicarbonate | 71.3 per cent |
| Sodium carbonate | 4.0 per cent |
| Sodium chloride | 0.2 per cent |
| Ammonia | 0.5 per cent |
| Moisture | 24.0 per cent |
| | 100.0 |

The theory of this process, usually given in text books, is that the ammonia first becomes bicarbonate and then decomposed the sodium chloride, sodium bicarbonate being precipitated. But if that was so the ammonium bicarbonate, being equally as insoluble as sodium bicarbonate, would be also precipitated. Besides much heat is absorbed in the reaction of ammonium bicarbonate with sodium chloride; whereas it is well known in practice that in the Solvay tower much heat is evolved, because the precipitation of sodium bicarbonate by carbonic acid from a solution of sodium carbonate is exothermic.

When this process was first introduced by Messrs. Dgar and Hemming it was stated that: To a concentrated solution of sodium chloride was added an equivalent quantity of ammonium sesquicarbonate in order to decompose it, and a current of carbonic acid gas passed through the mixture to saturate the ammonia to make decomposition as perfect as possible, and even an earlier worker, John Thom of Camlachie, Scotland, was said to have mixed the sodium chloride with ammonium sesquicarbonate in the dry, added water and then pressed the mixture.

Now it is well known that when ammonium sesquicarbonate is dissolved in water it is resolved into the neutral carbonate and the bicarbonate, and what happened in these early operations was that ammonium bicarbonate so formed decomposed the sodium chloride, sodium bicarbonate being precipitated, and even when further quantity of carbonic acid was added, it was found that only two-thirds of the sodium chloride has been decomposed. In the Schloesing method, where solid ammonium bicarbonate is treated with a solution of sodium chloride, only two-thirds of the sodium chloride are decomposed, and the same rate of decomposition is also found in the Solvay system.

The opinion of the author is that it is the effect of the ammonium chloride which decides the quantity of sodium chloride decomposed by weakening the action of the ammonium carbonate on the sodium chloride, for when the ammonium chloride is separated from the mother-liquor of the carbonating process and it is further treated with carbonic acid a much larger percentage of sodium chloride is decomposed.

Oxford, England.

---

**The metal production of Oregon in 1913** was valued at $1,746,402, an increase of more than 100 per cent over that of 1912. The Geological Survey states that copper was the only metal that did not show an increase in production. The gold yield was $1,627,710; silver, 179,036 fine oz.; copper, 43,330 lb.; lead, 87,207 lb.

**The quicksilver industry** showed decreased activity in 1913, according to figures compiled by the U. S. Geological Survey. With the exception of the production in 1908, that of 1913 was the lowest since 1860. The decline was due largely to increased foreign production, a dull market and lower prices. California was the largest producer, with 15,591 flasks of 75 lb. out of a total domestic production of 20,213 flasks. The rapid extension of the cyanide process for recovering gold and silver has materially affected the use of quicksilver for metallurgical purposes.

**The specific heat of copper** in the interval 0 deg. to 50 deg. C., with a note on vacuum-jacketed calorimeters, is the subject of a bulletin published by the U. S. Bureau of Standards. The bulletin was written by Mr. D. R. Harper, 3d. The determinations in the temperature range 0 deg. to 100 deg. are interpreted to indicate that the specific heat of copper (hard-drawn probably excepted) at 50 deg. is between 0.0926 and 0.0931.

# Refractometry

BY G. A. SHOOK

## I.—Fundamental Principles

*Refraction.*—Whenever a beam of monochromatic light passes from one medium, such as air, into another medium of a different *optical density*, such as glass, the beam will be bent out of its path. If the second medium has a greater optical density than the first the beam will be bent *toward the normal*, while if it is less dense it will be bent *away* from the normal to the interface, as shown in Fig. 1.

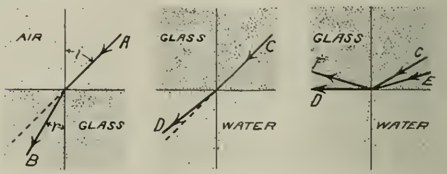

FIG. 1—REFRACTION

The amount of bending or *refracting* is slightly different for different substances. Practically all solids and liquids are optically denser than air and a few gases are optically rarer but there is no simple relation between optical density and mass density. The relation between the incident angle $i$ and the refracting angle $r$ is given by the simple formula

$$n = \frac{\sin i}{\sin r}$$

The constant $n$ is known as the *refractive index* and it is an important optical constant of liquids and solids. When light passes from a vacuum into any medium the ratio $\sin i/\sin r$ is called the *absolute index* of refraction, and when it passes from one medium into another, as from air to glass, it is called the *relative index*. Unless otherwise stated it is always understood that the angle of incidence is measured in air, that is, the word "relative" is usually omitted.

The index of refraction may also be defined in terms of the velocity of light in two different media. Thus, if we represent the velocity of light by $V$ the relative index for any substance, say glass, may be expressed by the relation

$$n_g \text{ (referred to air)} = \frac{V \text{ (in air)}}{V \text{ (in glass)}}$$

For the absolute index of air we have

$$n_a \text{ (referred to vacuum)} = \frac{V \text{ (in vacuo)}}{V \text{ (in air)}}$$

Whence the absolute index for glass is

$$n_g \text{ (referred to vacuum)} = \frac{V \text{ (in vacuo)}}{V \text{ (in glass)}}$$

$$= n_g \text{ (referred to air)} \times n_a \text{ (referred to vacuum)}$$

or

$$n_g \text{ (absolute)} = n_g \text{ (relative)} \times n_a$$

Hence if we know the index for air at the desired

TABLE I—REFRACTIVE INDICES

| Substance | °C | $n_d$ |
|---|---|---|
| Fluorspar | 18 | 1.4339 |
| Iceland spar | 18 | 1.6584 |
| Water | 20 | 1.33299 |
| Water | 30 | 1.33248 |
| Carbon bisulphide | 20 | 1.6277 |
| Ethyl alcohol (absolute) | 25 | 1.35941 |
| Ethyl alcohol (5% $H_2O$) | 25 | 1.36125 |
| Diamond | | 2.4699 |
| Cotton-seed oil | 15 | 1.4743 |
| Sesame oil | 15 | 1.4748 |
| Almond oil | 60 | 1.4555 |

temperature the absolute index of any substance may always be determined from its relative index. The refractive indices of a few common substances are given in Table I.

If the light in Fig. 1 were transmitted in the reverse direction *BA* instead of the direction *AB* it would follow the same path. The same is true for the path *CD*.

Now if the ray *C* is gradually oriented so that it makes a larger and larger angle with the normal, the ray *D* will likewise make with the normal a larger and larger angle and a position of *C* may be found such that the ray *D* passes along the interface as shown in the third diagram of Fig. 1.

The angle made by *C* and the normal in this case is called the *critical angle* of *incidence*. Moreover, if the light is transmitted at grazing incidents, i.e., if it passes in the direction *DC* then it will be bent into the glass as shown. The critical angle of water is about 48 deg., that of crown glass 42 deg., while that of diamond is only 24 deg.

If the incident ray makes a still larger angle, the ray *D* will be bent back into the first medium, as shown by the path *EF*.

When this condition obtains, no light is transmitted and the incident light is said to be *totally reflected*. The ray *EF* now obeys the ordinary law of reflection, i.e., the angle made by *F* and the normal is the same as the angle made by *E* and the normal.

It is not a simple matter to measure the angle of incidence and the angle of refraction directly with any accuracy, so that the index of refraction, *n*, is generally determined by some indirect method. When the substance can be formed into a prism with optically plane sides, which is seldom the case, then the refractive index may be determined in terms of the angle of the prism by means of an ordinary spectrometer.

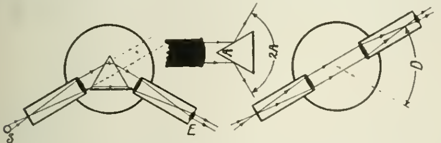

FIG. 2—SPECTROMETER METHOD OF DETERMINING THE INDEX OF REFRACTION

Light from a source of monochromatic radiation *S*, Fig. 2, such as a colorless gas flame in which some common salt is volatilized, falls upon the slit of the collimator and is rendered parallel by the collimator objective. This parallel beam is bent out of its path by means of a prism and thence passes through the telescope objective and forms an image of the slit. This image is finally observed by means of an eyepiece *E*.

To obtain the deviation angle one has only to set the cross-wires of the telescope on the image of the slit and to read the position of the telescope by means of the spectrometer circle when the beam is refracted by the prism and when the telescope is in line with the collimator.

The deviation, *D*, is always measured when the prism is set for *minimum deviation*; that is, when it is placed symmetrically with respect to both the incident and transmitted beams. If the prism were placed in any other position, then the deviation of the transmitted beam would be different for each position.

The position for minimum deviation is accurately obtained by adjusting the telescope and the prism so that the slit-image is in the field of view when the prism is approximately symmetrical to the collimator and to the telescope. It will now be found that upon rotating the prism slightly to the left the image passes to the left, stops, and returns to the right. This end-point, as it were, marks the position of *minimum deviation* and the cross-wires should then be set on the slit-image when the latter is in this position. This shift of the telescope, unless it is very slight, may necessitate a further small adjustment of the prism, and then again a slight movement of the telescope before the position is found such that on continuously rotating the prism to the left the image moves from the right just up to the cross-wires, stops, and returns again to the right.

The angle of the prism is obtained by setting it so that its base is approximately symmetrical with respect to the collimator as shown in Fig. 2, and then measuring the angle 2*A* by means of the telescope. The refractive index *n* in terms of the prism angle *A* and the deviation angle *D* is given by formula

$$n = \frac{\sin\left(\frac{A+D}{2}\right)}{\sin\left(\frac{A}{2}\right)}$$

This formula is only true when the prism is set for minimum deviation. To determine the refractive index of a liquid a hollow prism with plane parallel glass sides may be used, but there are other methods which are far more convenient.

The values of *n* thus determined depend only upon the color, or wave-length of the light used and they are always given for a particular color, generally yellow, the color of the sodium spectrum line. With a spectrometer of high resolving and dispersive power two sodium lines can be distinctly seen, and they are known as the *D* lines. The one that is the most refracted is designated $D_1$ and the other $D_2$. The wave-length of $D_1$ is 0.0000589 cm. and that of $D_2$ 0.00005896 cm. In refractometric measurements the mean of these two wave-lengths is variously written 5893A (Angström units), 0.5893μ (microns) and 0.00005893 cm.

In all cases it is necessary to specify for what wave-length the refractive index is determined and this may be done in any of the above ways. The variation of *n* with wave-length in the case of flint glass and carbon bisulphide is shown in Table III.

From Table I it is readily seen that the difference in *n* for different substances is so small that quite an accurate measurement is necessary in order to make the determination of this constant of any practical value in industrial work. While the spectrometer is used for absolute measurements it is not practical for industrial work since considerable care in manipulation is necessary in order to obtain accurate results and, moreover, to carry out a determination a large amount of the material to be tested is required.

Most of the instruments now in use utilize the phenomenon of total reflection. Some of these instruments are so constructed that white light may be used and a special illuminating device is therefore unnecessary, but with others monochromatic light must be used.

While it would be more logical to reduce all refractometric measurements to the refractive index, *n*, it is in some cases more convenient to give the refraction in terms of an arbitrary scale division. Most of the important instruments, however, that are provided with arbitrary scales are also provided with tables, so that the scale readings of a particular instrument can be converted into refractive indices.

In all work, therefore, it is very important to state the refraction in terms of the index and preferably for the *D* line. The user of any instrument provided with an arbitrary scale can readily transform refractive indices into scale divisions to suit his own work.

*Dispersion.*—If the ray of light *AB* incident on the interface, Fig. 1, is not monochromatic, i.e., not of a single color such as the yellow light emitted by a sodium flame then it will be spread out or *dispersed* in the second medium as shown in Fig. 3.

The blue rays are the most refrangible and the red the least.

The amount of spreading out and the extent to which all of the rays are refracted depends both upon the angle of incidence and the material of the medium. Thus for the same angle of incidence the refraction is different for water and for glass, but for the same material, say glass, the refraction is different for different angles of incidence.

When the slit of a spectrometer is illuminated by white light one sees, on looking through the telescope, a continuous succession of images of the slit; that is, the slit-image is drawn out into a band of color. Fraunhofer identified a large number of the most conspicuous absorption lines in the solar spectrum with the emission lines of familiar terrestrial elements and these are designated by the letters *A*, *B*, *C*, etc. The wave-lengths corresponding to a few of these lines are given in Table II

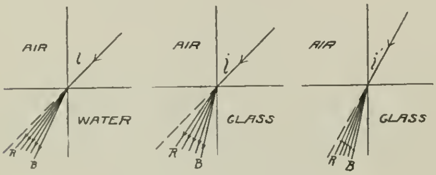

FIG. 3—DISPERSION

TABLE II—WAVE-LENGTHS OF THE FRAUNHOFER LINES

| | | | |
|---|---|---|---|
| A′ | 7677 A° | Red | K |
| A | 7605 | | |
| B | 6867 | | |
| C | 6563 | $H\alpha$ | Red |
| D | 5893 | Yellow | Na |
| E | 5270 | Green | |
| F | 4861 | $H\beta$ | Blue |
| G′ | 4341 | $H\gamma$ | " |
| h | 4103 | $H\delta$ | " |
| H | 3969 | | |
| K | 3934 | | |

In refractometry indices of refractions are generally referred to one of these lines. For the same wave-length interval the difference in angular deviation is by no means the same throughout the spectrum, but in general the shorter wave-lengths are separated the most. The difference between the refractive indices for any two wave-lengths or colors is called the *dispersion*. For a given substance the dispersion is different for different parts of the spectrum and for a given region of the spectrum the dispersion will be quite different for different substances. Thus for flint-glass the refractive index for the *C* line is 1.618 and that for the *D* line is 1.628, therefore the dispersion for the interval *D-C* is $n_d - n_c = 0.010$.

Since most of the visible spectrum is included between the *C* and *F* lines, the dispersion for this region, namely, $n_f - n_c$, is often taken as a characteristic constant of a solid or a liquid in the same way as we consider the refractive index for, say, the *D* line. This factor, $n_f - n_c$, is sometimes called the *mean dispersion* and sometimes the *medium dispersion*, while the interval $n_d - n_c$ or $n_f - n_g$, etc., is known as the *partial dispersion*.

Again, if the index of refraction is measured over any other range, say, from *A* to *H*, the dispersion $n_h - n_a$ is spoken of as the *medium dispersion*. Since the interval *C* to *F* comprises about all the visible spectrum, it is proportional to the dispersion of the entire visible spectrum, hence the notation *medi-dispersion*.

In general a substance which has a large $n_d$ will have a large medium dispersion, $n_f - n_c$, but this does not necessarily follow by any means. Let us consider, for example, the case of flint glass and carbon bisulphide. The indices for four lines are given in the following table:

TABLE III

| | Flint Glass | |
|---|---|---|
| C | 1.624 | 1.618 |
| D | 1.628 | 1.628 |
| F | 1.641 | 1.652 |
| H | 1.674 | 1.689 |

It is seen from this table that for the *D* line value of the index of refraction is the same in both cases, but the total dispersion for flint glass is 0.050 and for carbon bisulphide it is 0.071. Moreover, the partial dispersions for the two cases bear no simple relation to the complete dispersions.

The partial dispersions are, however, in each case greater for carbon bisulphide than for flint glass; that is, the large complete dispersion is accompanied with large partial dispersions, although there are even exceptions to this. In the case of carbon bisulphide and monobromonaphthaline the complete dispersion, *A* to *H*, for the latter is very much larger than for the former, while the partial dispersions *D* to *F* and *F* to *G′* are slightly less.

From the data on Jena glass, Table IV, it is seen that while the second substance has a slightly larger mean dispersion than the first its refraction for the *D* line is much less. Moreover, while the third substance has a higher mean dispersion than the second its index of refraction for the *D* line is larger than the second.

TABLE IV—JENA GLASS

| | $n_d$ | Mean Dispersion C to F |
|---|---|---|
| Medium phosphate crown | 1.5590 | 0.00835 |
| Silicate crown | 1.5109 | 0.00844 |
| Crown of high dispersion | 1.5149 | 0.00943 |

Manifestly one cannot infer that because the refraction for the *D* line is high the total dispersion will consequently be high, or conversely.

It is thus seen from the above examples that dispersion plays an important rôle. For instance, two substances under analysis may give the same value for $n_d$, but they may not show the same mean dispersion so that while a determination of $n_d$ would not tell us anything of the composition of a particular substance, a measurement of its dispersion might be of value.

*Index Refraction and Density.*—That the index of refraction varies considerably with the physical state of a substance has been known from the beginning of the history of light theories. The two most important changes are density and temperature. Laplace derived, from the emission theory of light, the expression

$$\frac{n^2 - 1}{d} = k = \text{const.}$$

Considerably later Gladstone and Dale determined empirically the relation

$$\frac{n - 1}{d} = k' = \text{const.}$$

Finally a third formula

$$\frac{n^2 - 1}{d\,(n^2 + 2)} = k'' = \text{const.}$$

was deduced from Maxwell's magnetic theory of light by a number of physicists.

These formulæ have been tested by many experiments, but most of the data has been derived from liquids. The temperature correction for either of these formulæ is small and is generally neglected except in refined work. The last two equations are now more generally used than the first and the second is preferable because of its simplicity.

The constant $k$, $k'$ or $k''$ is sometimes called the *specific refractive power* and the product of the specific refractive power and the molecular weight of a substance is called the *molecular refractive power*.

In the case of an organic solution or an electrolyte the refractive index does not increase at the same rate as the concentration. This may be due to the fact that hydration generally takes place.

Moreover, when a salt is dissolved in water the change in volume per unit quantity of salt is different for different concentrations. Therefore, when the density changes due to a change in concentration the refraction may still be a linear function of the density while it bears no simple relation to the concentration. If the concentration is, however, a linear function of the density, which is sometimes the case for limited ranges of concentration, then the refraction will increase at the same rate as the concentration. The above equations will also hold true when a change of density is effected by a temperature change.

When a salt is dissolved in water, the relation between the specific refraction of the salt $k$, that of the water $k_w$, and that of the solution $k_s$ is given by the simple relation

$$kx + k_w\ (100 - x) = 100\ k_s$$

where $x$ is the per cent of concentration. Assuming that $k_w$ does not change when the salt is dissolved into it, the specific refraction $k$ may be determined from a measurement of the refractive index of the solution.

Moreover, the sum of the *atomic* refractions of the elements of a compound is equal to the *molecular* refraction of the compound and this relation may be expressed by the simple equation

$$R = xr + x'r' + x''r'' \quad . \ . \ . \ .$$

where $R$ is the molecular refraction, $r$ is the atomic refraction, and $x$ the number of atoms that enter into composition.

In Table V are given the molecular refractions of lithium chloride, sodium chloride, etc. This data was taken from the works of Baxter, Boylston and others on "The Refractive Powers of the Halogen Salts of Lithium, Iodine and Potassium in Aqueous Solutions." This work was carried out with a Pulfrich refractometer and by means of a *differential method* an accuracy of two units in the fifth decimal place was obtained. The values given in Table V are all for the same concentration.

TABLE V—MOLECULAR REFRACTIVE POWERS

| | cl | Br | I |
|---|---|---|---|
| Li | 8.75 | 12.29 | 19.00 |
| Na | 9.25 | 12.80 | 19.43 |
| K | 11.35 | 14.19 | 21.48 |

This additive law of the atomic refractions has been the subject of much discussion and it is apparently only approximately true. We may at least, however, get a rough estimate of the molecular or atomic refraction of a number of elements that could not be determined otherwise. An example may be worked out from the above data. Since the molecular refraction varies slightly for different concentrations it is logical to compare only values obtained for the same concentration.

The value of the atomic refraction of hydrogen obtained for the $D$ line is 1.03 and a recent value for the molecular refraction of hydrogen chloride is 8.53, therefore, the atomic refraction of chlorine is $8.53 - 1.03 = 7.50$.

We may now write

$$r\ (\text{Na}) + r\ (\text{Br}) = 12.80$$

and

$$r\ (\text{Na}) + r\ (\text{Cl}) = 9.25$$

whence

$$r\ (\text{Br}) - r\ (\text{Cl}) = 3.55$$

or

$$r\ (\text{Br}) = r\ (\text{Cl}) + 3.55 = 7.50 + 3.55 = 11.05$$

In a similar manner we obtain for iodine

$$r\ (\text{I}) = 17.68$$

We can also determine the atomic refraction of Li, Na, or K. For example, the molecular refraction of NaCl is 9.25, whence the atomic refraction of Na is $9.25 - 7.50 = 1.25$. We may, of course, determine the atomic refraction of Na from NaBr or NaI.

*Index of Refraction and Temperature.*—The relation between the refractive index and the temperature of a substance is practically linear and may be expressed by the formula

$$\frac{n}{a} + \frac{t}{b} = 1.$$

That is, the change in the index of refraction from 20 deg C. to 21 deg. C. is the same as the change from, say, 42 deg. C. to 43 deg. C, etc.

The constants $a$ and $b$ must be determined for a particular wave-length of light and they will also be different for different substances, although for certain classes of liquids, for example, the ordinary oils and fats, the change in index of refraction per degree C. is practically the same as is shown in Table VI (Tolman and Munson):

TABLE VI—TEMPERATURE CORRECTIONS FOR OILS

| Oil | Decrease in index per °C |
|---|---|
| Linseed | 0.00037 |
| Cotton | 0.00037 |
| Peanut | 0.00037 |
| Corn | 0.00036 |
| Sesame | 0.00037 |
| Olive | 0.00037 |
| Rape | 0.00036 |
| Mean value | 0.000365 |

If, therefore, the refractive index of an oil is 1.47365 at 20 deg. C., at 30 deg. C. it will be 1.47000.

In the case of instruments constructed with arbitrary scales, each division of the scale does not represent necessarily the same increment of refraction so that different corrections must be applied to different parts of such a scale. This will be considered in the next article on Instruments.

Although a temperature correction can be effected, it is always desirable to carry out the determination of the refractive index at some fixed temperature, say, 25 deg. C. This is not possible for two reasons; in the first place, while an instrument may be maintained at a constant temperature without much difficulty, rather elaborate heating apparatus is necessary in order to control the temperature, and, secondly, tables of indices of refraction are not made out for a standard temperature, so that data must be taken for whatever temperature it has been worked out and the necessary temperature correction made.

That the temperature correction changes markedly with the wave-length of the light used is shown clearly by Table VII on dimethylaniline (Falk).

TABLE VII—REFRACTION INDEX OF DIMETHYLANILINE AND TEMPERATURE

| Spectral line | Index of refraction | Change per °C |
|---|---|---|
| C | 1.55296 | 0.000495 |
| D | 1.55968 | 0.000499 |
| F | 1.57765 | 0.000519 |
| G' | 1.59489 | 0.000539 |
| Density | ..... | 0.000825 |

The change which takes place in the dispersion with temperature change is also of interest (Table VIII).

TABLE VIII—DISPERSION AND TEMPERATURE

| | D-C | F-D | G'-F |
|---|---|---|---|
| Dispersion at 10° | 0.00666 | 0.01810 | 0.01722 |
| Dispersion at 80° | 0.00638 | 0.01670 | 0.01582 |

*Density and Temperature.*—The variation of density with the temperature may also be expressed by an equation of the form

$$\frac{d}{a'} + \frac{t}{b'} = 1$$

The effect of temperature change upon refractive index, density, and the specific refraction is shown in Table IX, taken from the work of Falk. This work was all carried out by means of a Pulfrich refractometer.

TABLE IX—DIMETHYLANILINE

| C | $n_c$ | $d$ | $k$ | $k'$ | $k''$ |
|---|---|---|---|---|---|
| 10 | 1.55680 | 0.9648 | 1.4756 | 0.5771 | 0.3335 |
| 40 | 1.54195 | 0.9401 | 1.4654 | 0.5765 | 0.3347 |
| 80 | 1.52215 | 0.9070 | 1.4520 | 0.5757 | 0.3363 |

The density of a solution is, of course, not a simple function of the concentration and therefore there is no simple relation between index of refraction and concentration.

In many cases, however, by means of tables, the concentration can be determined from the density. Since the index of refraction of a liquid can be accurately determined with far greater ease than the density, it is often advantageous to estimate concentrations by means of the refractometer.

In the case of aqueous alcohols, tables have been worked out giving the per cent of water in terms of the refractive index or in terms of the scale divisions of some particular instrument, for instance, the Zeiss refractometer, which is particularly adapted to alcohols. In Table X a few values of such a concentration table (Andrews) are given.

TABLE X—ALCOHOL

| % $H_2O$ | $N_d$ at 25° C | Zeiss Reading |
|---|---|---|
| 0 | 1.35941 | 85.30 |
| 1 | 1.35984 | 86.49 |
| 2 | 1.36024 | 87.60 |
| 3 | 1.36061 | 88.63 |
| 4 | 1.36094 | 89.59 |
| 5 | 1.36125 | 90.45 |

It will be observed from this table that the difference in the Zeiss reading for small changes in concentration is sufficiently large to permit a very accurate determination of the concentration. As might be expected, there is not a constant difference in index of refraction for each per cent difference in concentration. The maximum value of the index is for a solution containing 20.7 per cent $H_2O$.

Another important use of the refractometer, in the case of alcohols, is the determination of the amount of methyl alcohol present in any mixture of ethyl and methyl alcohol. Here a determination of the density is of no value whatever, since the density of absolute methyl and absolute ethyl alcohol is practically the same. Moreover, when they are diluted with the same amounts of water their densities are identical. However, the refraction for ethyl alcohol is much greater than the refraction for methyl alcohol.

From a table given by Leach and Lythgoe, who were the first to make out data for alcohols, a 20 per cent solution of methyl alcohol gives a Zeiss reading of 26.5, while the same concentration of ethyl alcohol gives a reading of 50.5, and the two readings corresponding to a 50 per cent solution are 39.8 and 90.3. For small concentrations the difference is not so great.

It is thus seen that it is a comparatively easy matter to identify the two alcohols by means of the refractometer. If, therefore, the strength of a solution of alcohol is determined from its density, by means of such a table one can determine at once whether the alcohol is methyl or ethyl. Moreover, if it is a mixture, a simple calculation will enable one to determine the per cent of each present.

One of the examples that they give may be of interest. From the analysis of a lemon extract an 18.38 per cent alcohol was found and it gave a reading of 35.8 on the Zeiss refractometer. From their table the readings corresponding to an 18.38 per cent alcohol are 47.2 for ethyl and 25.4 for methyl alcohol. Assuming that the addition of methyl alcohol to ethyl alcohol decreases the refraction in direct proportion to the amount added, the per cent of the methyl alcohol present in the mixture is evidently

$$\frac{47.2 - 35.8}{47.2 - 25.4} \times 100. = 52.3.$$

This classical example is cited to illustrate the use of the refractometer where other simple methods of analysis fail.

No references have been given to tables of indices of refraction, temperature corrections, etc., since these may always be found in books on food analysis or in such standard works as the Landolt-Börnstein Physickalisch-Chemische Tabellen.

Professor Féry has prepared tables of refractive indices of the chief solutions of salts employed in laboratories. Such observers as Chéneveau, Bary, Labrosse, Lebrasseur and Grassot, Warrick (London), Coffignier, Dr. Nicloux, Professor Demerliac, Tixier have also added to the earlier tables and their results are published in part in the Memento du Chimiste of MM. A. Haller and Ch. Girard.

Among other things of importance included in these tables are the following:

Solutions of sulphuric, nitric, hydrochloric and acetic acids.

Alkaline solutions of sodium and potassium.

Solutions of sodium carbonate, of the chlorides of sodium, potassium, ammonium, and zinc.

Solutions of the sulphates of iron, copper, zinc, aluminium and lithium, of potassium bichromate and hyposulphite of sodium.

Mixtures of water and alcohol (ethyl and methyl).

Mixtures of water and glycerine.

Solutions of citric, tartaric, oxalic and tannic acids.

Refractive indices of various organic compounds, refractive indices of essential oils employed in perfumery.

Various other oils, of which a large number of tables have been prepared owing to the industrial importance of this method of analysis.

**Chlorate of Potash in Norway.**—The Frederiksstad Elektrokemiske Fabriker have acquired a secret process for the production of potassium chlorate, in commercial use at present in the south of Europe. Norway has imported heretofore some hundred tons of this product a year. Similar factories, using older processes, are in operation in Finland and in Sweden. The Frederiksstad Elektrokemiske Fabriker has met with much sympathy from the town of Frederiksstad whereby they have secured a favorable power contract under the contract of the town of Frederiksstad with the power company of Hafslund.

The **De Laval Separator Company**, New York, have installed an experimental creamery, as part of their experimental department, in Poughkeepsie, N. Y. It is probably the only creamery in the United States where practically all the milk is separated by hand separators. In addition to cooling vats, pasteurizers, Babcock testers, etc., it also includes the necessary apparatus for making chemical analyses, acid determinations, and physiological investigations and is equipped with special apparatus designed particularly for making delicate tests.

# Titanium-Nitride in Steel

BY GEORGE F. COMSTOCK

In the course of many microscopic examinations of rail steel, both untreated and treated with ferro carbon-titanium, certain hard non-metallic spots came to be recognized as being fairly characteristic of the treated steel and never found in the untreated. These spots were usually very minute, requiring a magnification of at least 200 diameters (preferably 400) to show them clearly; they were never found segregated in streaks or groups, but were always quite evenly scattered throughout the rail's section; they were never elongated in the direction of rolling, but often had angular outlines though usually somewhat rounded in shape; it was difficult to polish a sample containing these spots without pitting, owing to their great hardness as compared with the surrounding metal; and finally when seen with the pure white light of a carbon arc on the ground glass of the metallographic camera, these spots appeared bright pink in color. Their apparent hardness and color were their most characteristic qualities, and it was found that practically all titanium-treated rails contained these pink spots in varying amounts, except those in which the titanium had not produced its usual effect in reducing segregation. The above statement is based on our experience with about forty plain and treated "A" rails (rails made from the top parts of ingots), which have been thoroughly tested and examined here.

The photomicrographs of Figs. 1 and 2 show some of the typical pink inclusions as found in treated rail steel. The section from which these photomicrographs were made was cut parallel to the direction of rolling of the rail, and the lack of elongation of the angular pink inclusions is well shown by comparison with the long thin streaks of manganese sulphide.

The fact that these pink inclusions are never found in steel that has not been treated with titanium proves that titanium must be necessary for their production. An attempt has been made to discover the composition of this hard pink substance, but owing to its finely divided condition and the very minute quantity present in any given sample of treated steel, no pure sample could be obtained for direct chemical analysis. The method followed in attacking this problem was the rather crude one of incorporating various compounds of titanium in samples of untreated rail steels until some substance was found which appeared similar in all respects in a polished section to the characteristic "pink inclusions." Titanium sulphide, carbide and nitride naturally suggested themselves as the compounds most worthy of a trial, and it was also suggested that the spots might be alumina colored by titanium in some form. Practically all the melts of steel with the above compounds were made at the Rensselaer Polytechnic Institute at Troy, N. Y., by Prof. M. A. Hunter, and the titanium sulphide, carbide and nitride used were also supplied by him. The melts were made in an electric furnace in a vacuum, the residual atmosphere in the furnace being carbon monoxide.

The sulphide of titanium was the first compound investigated, and some untreated rail steel was treated with it, but the pink inclusions were not found. Photomicrograph 3 shows this steel as melted by Prof. Hunter in a carbon crucible without any addition. Ordinary manganese sulphide inclusions were numerous in it. Fig. 4 shows this same steel treated in an alundum crucible with ferro carbon-titanium. The characteristic pink inclusions were found here, and are represented in the photomicrograph by the dark angular spots. The faint small rounded spots were also pink in color, but much paler, and are probably some different substance, the identity of which is not important since these pale pinkish rounded spots are not found in ordinary steel. Fig. 5 shows this same steel treated in a carbon crucible with titanium sulphide, and Fig. 6 shows the result of the same treatment done in an alundum crucible. The spots shown in both these photomicrographs had the grayish color typical of manganese sulphide. By comparison with Fig. 3 it is seen that the addition of titanium sulphide to the steel has increased the amount of the ordinary sulphide inclusions and has caused them to be more finely divided, although their color was not changed. Evidently therefore titanium sulphide must mix with the manganese and iron sulphides if it is present at all in melted steel, and it cannot be the substance forming the "pink inclusions."

Titanium carbide was the next substance tried in the endeavor to find the composition of these inclusions. Fig. 7 shows the structure of some fairly pure titanium carbide. The large rounded grains there shown are of a pale violet color, while the streaks between them are very light yellow. The entire mass is very hard and brittle, and the black spots are pits broken out in grinding the section, and which could not be entirely removed in polishing. The violet gray material is the carbide of titanium, and the yellowish material is probably iron carbide or cementite. Fig. 8 shows some steel that was treated with titanium carbide. The smooth areas near the top of the print are carbide, and the spotted substance at the bottom is the steel, full of little dots of carbide. At the boundaries between the large masses of carbide and the steel a feathery, mixed structure was found, as shown throughout the center of this print. This peculiar appearance of the boundaries, together with the occurrence of the small spots of carbide through the steel, indicates that the carbide dissolved in the melted steel, and was more soluble when hot than when cold. Had the mixture been kept long enough at a high temperature, the carbide would eventually have become evenly distributed throughout the steel. None of the characteristic "pink inclusions" were found in this metal, and therefore they cannot be titanium carbide.

The structure of impure titanium nitride is shown by Fig. 9. This substance like the carbide, is very hard and brittle, and it is very difficult to remove by polishing the pits formed in it when the section is ground. The chief part of this alloy, appearing dark gray in the photomicrograph, is bright yellow in color and is probably pure nitride. The light areas shown in the photomicrograph probably represent carbide, and the black areas oxide.

Figs. 10 to 13, inclusive, show samples of rail steel treated with large amounts of titanium nitride. Fig. 10 shows a melt made by Prof. Hunter in an alundum crucible in a vacuum furnace, a large angular fragment of nitride being shown embedded in the steel. This fragment had the characteristic pink color and hard appearance of the "pink inclusions," and smaller typical "pink inclusions" were found scattered in the steel. This steel was from an untreated rail, which had previously been carefully examined and found free from pink spots, like all other untreated steels. Thus the remelting with titanium nitride produced in this case the typical "pink inclusions." In other parts of this small melt some ordinary yellow nitride masses were found, and since the melt was made in an alundum crucible, it was thought possible that the pink color might have been produced only where alumina from the crucible (or perhaps in the original steel) had combined with the titanium or the nitride.

In order to obtain a melt free from alumina as well as from carbon in excess, a small crucible was made from a piece of rail which was known to contain no alumina, and in it some nitride and drillings from the same steel were fused by an arc from an electrode rod of the same alumina-free steel. In this way it was certain that no alumina could be in the product, and the only carbon present was that in the steel used which was from a Bessemer rail. Photomicrographs Nos. 11, 12 and 13 show portions of this melt. In places the nitride seemed to have preserved its original yellow color, but a large amount of it showed the characteristic bright pink color of the "pink inclusions." In places this pink nitride was extensively marked with a dark gray substance, which is believed to be oxide, and Fig. 11 shows the structure where the dark substance was specially abundant. The color of the nitride even here where it was so much oxidized was on the whole distinctly pink. Fig. 12 shows a part of the melt where there was less oxide, and where some smaller particles of the pink nitride were embedded separately in the steel. The steel near the large masses of nitride was full of very small pink inclusions, showing that the nitride dissolved in the steel to a slight extent. Fig. 13 shows some of these very small but typically pink inclusions. It must be remembered, however, that this melt was made with an electric arc, so that extemely high tempeatures were attained in parts of the crucible. Photomicrograph, Fig. 10, compared with Fig. 8, shows that at temperatures sufficient to melt steel the nitride does not readily dissolve while the carbide does.

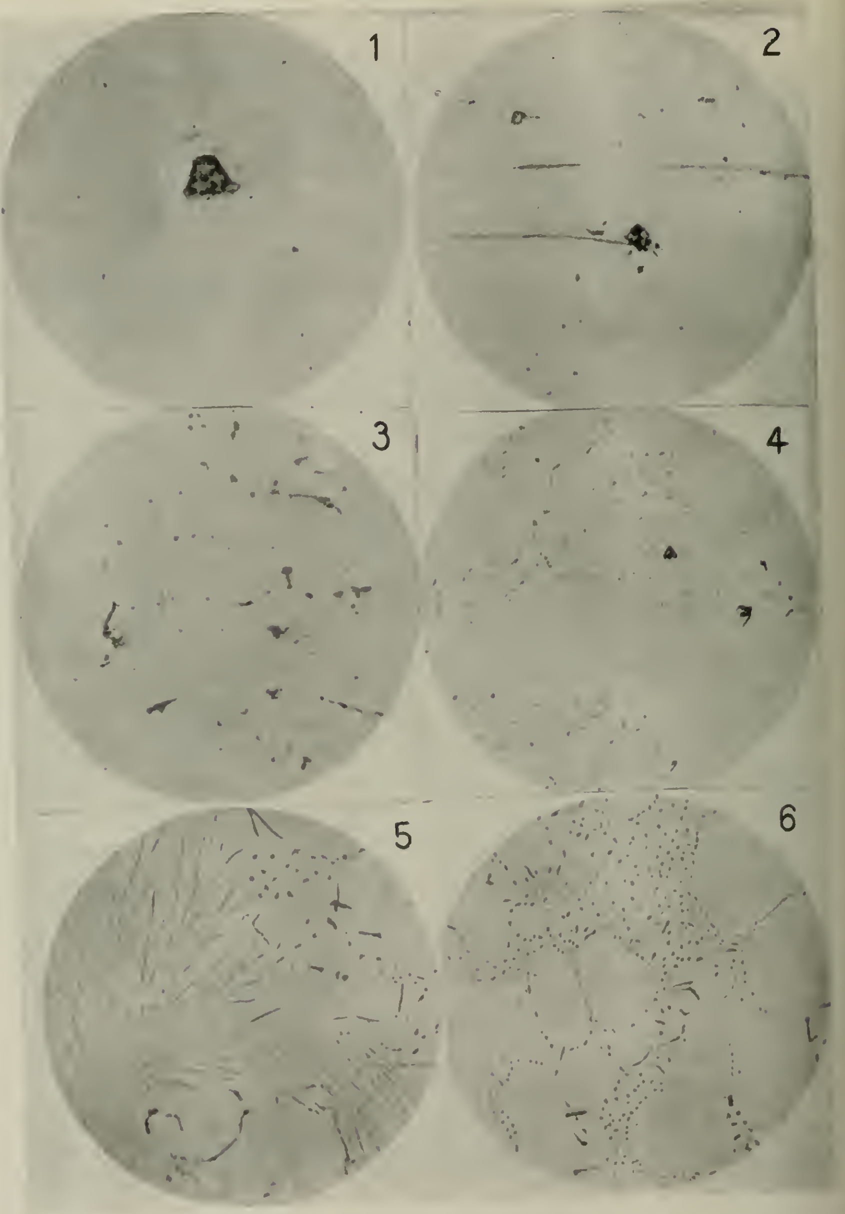

Fig. 1: Longitudinal section in web of titanium-treated rail, magnified 400 diameters, showing angular pink inclusion. Fig. 2. Longitudinal section in web of titanium-treated rail, magnified 400 diameters, showing angular pink inclusions and long fibres of manganese sulphide. Fig. 3: Untreated steel, with manganese sulphide inclusions, magnified 200 diameters. Fig. 4: Treated steel with two kinds of pink inclusions, pale and darker, magnified 200 diameters. Fig. 5: Steel containing manganese and titanium sulphides, magnified 200 diameters. Fig. 6: Steel containing manganese and titanium sulphides, magnified 200 diameters.

Fig. 14 shows a large skeleton crystal, found in ferrotitanium, made by the alumninothermic method, which had the characteristic color of the "pink inclusions." By dissolving this alloy in acid a residue was obtained of yellowish pink crystals which were found to contain nitrogen. This is in agreement with the view that the pink crystals found in steel are titanium nitride.

It seems evident from the above experiments that the "pink inclusions" found in titanium-treated rail steel,

and not found in untreated steel, are composed largely if not entirely of titanium nitride, and that while carbon and iron may enter into their composition, alumina does not. Photomicrographs Figs. 15 and 16 are of interest in this connection. Fig. 15 shows an alloy of "pure" Swedish iron with 5 per cent of pure metallic titanium, and Fig. 16 shows a similar alloy of Swedish iron with ½ per cent of aluminothermic ferrotitanium alloy. These alloys were melted in a vacuum furnace and in alundum crucibles. The angular inclusions shown in Fig. 15 had the yellow color of titanium nitride, and the small rounded spots were very pale pink like the inclusions shown in Fig. 4. The metallic titanium must have combined with the nitrogen in the Swedish iron to form the yellow nitride, and possibly the total absence of carbon from this alloy is the reason for the pink color not being shown. Photomicrograph 16 shows a streak of alumina inclusions, their color being very dark blue. No pink or yellow inclusions were seen in this alloy, although some titanium was present with aluminium. Alumina has been identified in ordinary steels and occurs in very small dark bluish particles, very hard to polish without pitting, and often arranged in streaks.

It is unfortunate that chemical confirmation cannot be obtained for the identification of the "pink inclusions" as titanium nitride, but no reliable method is known for the quantitative determination of nitrogen in this form. An average of many nitrogen determinations made here by an improved method on titanium-treated rails shows a distinctly lower amount present than in untreated rails, but this difference in nitrogen content of the metal may be due to the locking up of some nitrogen by titanium in the pink inclusions, or to the actual removal of nitrogen from the liquid steel bath,

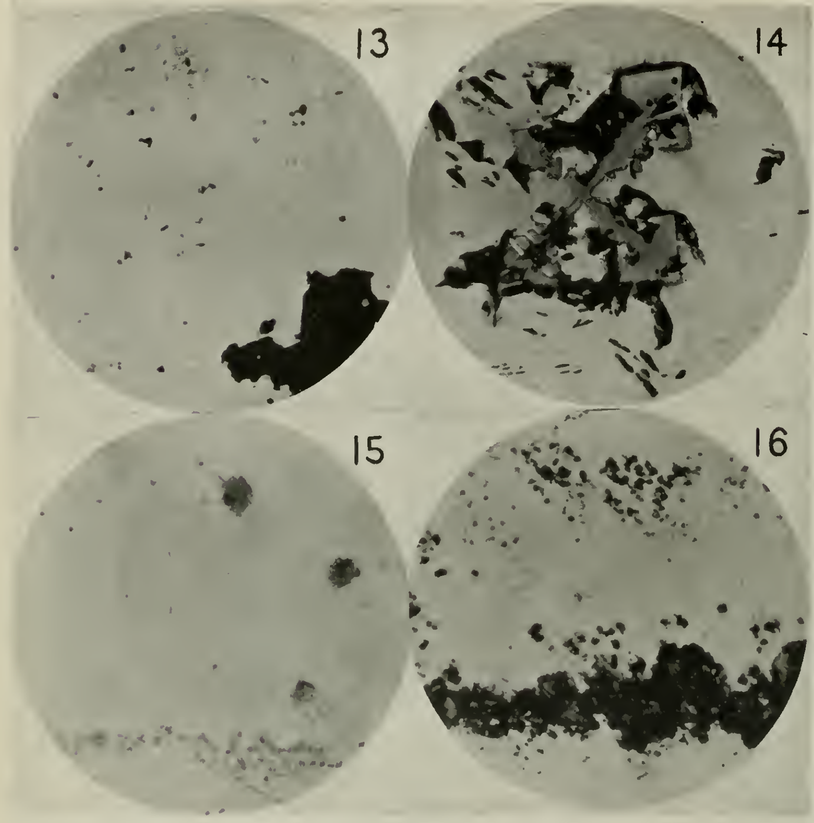

Fig. 13: Pink inclusions of titanium nitride in steel, magnified 400 diameters. Fig. 14: Crystal of pink titanium nitride in aluminothermic ferrotitanium, magnified 200 diameters. Fig. 15: Pure 5% ferro-titanium, with yellow nitride crystals, magnified 400 diameters. Fig. 16. Alumina from aluminothermic alloy in iron, dark blue in color, magnified 400 diameters.

or to both effects combined. At any rate, if it is assumed that nitrogen has an injurious effect on steel, the lower amount found by analysis must be an advantage, for even if the whole amount removed from the metal itself is still present in the pink inclusions, it could have no more ill effect in this form than any other non-metallic inclusions of the same size. As the titanium nitride inclusions are never found segregated in groups or streaks, but are always very small, scarce and thinly scattered, their weakening effect on the metal is practically negligible. It is hardly possible that the nitrogen contained in the pink inclusions could have been derived from any other source than the bath of steel to which the titanium was added, as the regular ferro carbon-titanium does not show these pink spots. Therefore their presence in a treated steel must mean that some nitrogen has been removed from solution in the metal, and this removal must be a distinct benefit, if as some authorities claim, nitrogen is very injurious when dissolved in steel.

The fact that titanium nitride is present in certain steels must not be taken to mean that all the titanium found in them by chemical analysis is present in that form. Some of it, of course, must be, but the quantitative estimation of this compound in a given steel is a problem that has not yet been solved either chemically or otherwise. It is entirely possible that a considerable amount of titanium may be present as carbide in steels that contain the pink nitride inclusions, as well as in those that do not.

It has been found in examining a great many titanium-treated rails, that, in all except a few which contained no titanium nitride, the sulphide inclusions were smaller and more evenly distributed than in the untreated rails. This is a fact which it is hard to explain theoretically, but an interesting confirmation is shown by the steel treated with titanium sulphide (Photomicrographs 3, 5 and 6), which showed much finer sulphide inclusions than the same steel untreated.

This work is described and published with a view chiefly toward interesting metallographists and aiding them in identifying the pink titanium nitride crystals. It is believed that they have not been described before in the literature of non-metallic inclusions in steel, and a familiarity with their appearance and composition should be valuable as affording a means of knowing that steels in which they are found had been treated with titanium.

The conclusions to be drawn from the work described above are that these hard pink inclusions are composed chiefly if not entirely of titanium nitride, and that while they may also contain some carbon or iron, alumina is not necessary for their formation.

**Foot-Rule.**—A four-joint two-foot rule of Starrett make is being sent by the Ashland Fire Brick Company of Ashland, Ky., to its friends on request. It is a very attractive and useful souvenir.

**The probable increase in tin production** in the Malay peninsula, due to the introduction of dredges and modern methods of production, is the subject of editorial comment in the *Malayan Tin & Rubber Journal*. This authority anticipates that, as the result of increased output, the price of tin will reach a lower level in the next two years. Nineteen dredges are now at work, and as many more are to be built.

**Idaho's output** of gold, silver, copper, lead and zinc in 1913 was valued at $24,149,049, according to the Geological Survey. The production of all metals except gold increased. The Coeur d'Alene region showed a marked increase in production of silver, lead and zinc.

# The Electric Arc Furnace and the Development of the Steel Casting Industry

BY IVAR RENNERFELT

Recently a very interesting article written by Mr. G. Muntz appeared in the METALLURGICAL AND CHEMICAL ENGINEERING (June, 1914). Its object was to call attention to the special features of the converter process for making steel castings and to compare this older method with the new electric process for melting steel, which is rapidly forcing its way to the front.

It may be well worth while to investigate the correctness of several of the points brought forward in said article in favor of the converter process, as the reader, unless familiar with the modern electric arc furnace, is liable to get an erroneous idea of the relative merits of the two processes. Of course, no one will or even can deny that the small bessemer converter has assisted greatly in developing the steel foundry, but it is also undeniable that the converter has drawbacks due to its construction and to the limited range of materials for which it is adapted.

The electric furnace, on the other hand, although a comparatively new tool, has already proven itself to possess advantages which are sure to open for it a very wide field of operation. Even if we know something about electric steel melting, more remains to be discovered and invented before we have fully demonstrated its many possibilities. The first practical electric furnace for melting steel was started hardly a decade ago and it is, therefore, difficult to forecast what will be the development of the next ten years. Most of the difficulties have been overcome and rules for the design of the electric furnace have been established on the basis of a considerable practical experience with a number of different types, used for different purposes.

### Economy

The first condition for economical melting of steel electrically is cheap energy. Hydroelectric power is generally the cheapest; but even medium-size steam or gas-power stations should be able to generate and sell energy at a cost sufficiently low to justify the running of a steel furnace. For the economical working of a steel foundry the continuity of operation is, however, an equally important factor at least if power is bought on the kw-year basis.

It has been found that an electrical steel foundry is well able to pay 1 cent per kw-hr. and still make a handsome profit, especially if a fair proportion of the output consists of light or difficult castings which will bring a good price per pound.

It is certainly to be expected that a well-situated and carefully managed central station can sell furnace energy at 0.5 cent per kw-hr. without losing money.

### Ease of Operation

The electric arc furnace, if properly designed, is very easy to handle. It will melt any kind of iron or scrap that is put into it rapidly and without oxidation. No special haste to discharge the furnace after the heat is completed is necessary as the charge may be kept in the furnace for any length of time without any material change in its composition. As a matter of fact, the steel is really improved by remaining in the hearth for some time before pouring as slag and gases thereby are given an additional chance to rise to the surface, rendering the steel more homogeneous and solid. This method of treating a ready charge of steel would be entirely out of question in the bessemer converter or the open-hearth furnace.

Should the molding work so demand, the pouring off may, therefore, be delayed and the steel delivered as required. The converter steel, on the contrary, must be teemed as soon as possible after completion of the heat, as it is impossible to maintain for any length of time the temperature required for making good castings.

### Refining Possibilities

The electric furnace is especially a refining tool by means of which the poorest kind of scrap iron may be transformed economically into the highest grade of cast steel. No other furnace can compete with the electric furnace in this respect.

The acid bessemer converter can deal only with a premelted charge of high-quality pig iron of closely limited composition, which determines the quality of scrap of high grade which may be added in the converter. In the acid open-hearth process we find the same reactions, but under better control, and with a wide range of raw materials. The basic open-hearth can deal with impure, low-grade materials and can to a certain extent reduce P and S. But neither of the above processes has as wide a range or as perfect control of the results as the electric arc furnace in which any element entering into the charge can be eliminated, practically to any extent desired.

### Remelting Foundry Scrap

In every steel foundry a considerable precentage of metal melted remains in the form of risers, runners, lost castings, etc. This refined metal is very conveniently remelted in the electric furnace and constitutes a first-class raw material. The proper composition of the charge is easily controlled by adding pure ore or mill scale to reduce carbon or pig iron, coke or coal to increase it. There does not exist the slightest difficulty in controlling carbon and the opinion of Mr. Muntz on this point is decidedly not warranted by the actual facts. If properly used, the electric furnace permits a much closer control of all the elements of a charge than any other melting apparatus, not even barring the crucible in which the control of carbon, silicon and manganese is far from easy.

The use of the Tropenas or Bessemer converter is limited by the quality of the raw materials, as every one familiar with metallurgical operations knows. The pig iron must be very high grade, low in P and S and high in Si and Mn. The machinery builders are continually raising their standards and will soon not be satisfied with steel castings containing any considerable amount of the ill reputed elements S and P. The cupola melting of the pig is always liable to introduce a certain amount of S into the pig iron, as all ordinary coke holds a good deal of this dangerous element.

### Smaller Loss from Oxidation

It is well known that in a well-designed and closed electric furnace a neutral or even a reducing atmosphere may be maintained.

No air enters the furnace and should any enter, when the door is opened, its oxygen will soon be consumed by the carbon of the white-hot electrodes. If the charge consists of pure steel scrap, practically no loss will take place as there is no oxidation. This is, of course, a very valuable feature, especially if the furnace is used for making alloyed steel castings from high-priced raw materials, which as a rule are very easily oxidized.

The converter is, contrary to this, known to cause a very considerable loss on account of oxidation. The raw material is twice exposed to the influence of the oxygen; first in the cupola and then in the converter. It is stated that with a small converter this loss amounts to not less than 12 to 15 per cent even with careful management. The loss may, however, under favorable conditions amount to even 28 to 31 per cent (Manual of the Metallurgy of Iron, Prof. E. G. son Odelstierna, Stockholm, 1913).

This loss means not only high cost, the pig iron used being high-grade and expensive, but it also introduces an undesirable uncertainty regarding the chemical composition of the steel. The pig iron used should contain 1.5 to 2 per cent Si but not more than 0.2 to 05 Mn in order to save the lining of the converter which would suffer considerably if the charge contained more Mn. These two elements Si and Mn serve as the source of heat in the converter and are, of course, a very expensive fuel. The converter process is liable to cause a considerable amount of scrap due to the low temperature of the steel in the ladle, risers and defective castings, which has to be remelted in the cupola. If this amount is large the molten cupola metal is liable to run low in Si and Mn and may, therefore, not produce steel of the proper temperature for casting it in molds.

The electric furnace is entirely independent of what percentage of scrap is put into it and can even run on scrap only. In this case the loss by oxidation is insignificant, provided that the scrap charged is clean and free from rust.

### The Supply of Raw Material

It has been supposed that a more general application of electric furnaces to foundry purposes would cause a shortage of steel scrap, raising the price of raw material to a prohibitive limit. It is, however, hardly possible that a prohibitive rise in price of scrap will be caused by the electric furnace as this is able to convert almost any kind of scrap, even such as is practically unfit for use in the open-hearth furnace which is by far the largest consumer of steel scrap. Should a rise take place, this will, therefore, more seriously affect the open-hearth steel plants and most likely a number of these plants may be replaced by bessemer converter works supplemented by electric refining and deoxidizing furnaces. Such a transformation would make large quantities of scrap available for the electric smelting furnaces at probably even lower prices than now paid by the steel works.

But the electric furnace is also suitable for the pig and ore process, receiving molten or melting a charge of pig to which is added enough ore to decarbonize the charge. For this method the consumption of energy is not prohibitive. According to tests made by the Ljusne Ironworks in Sweden it may be expected that steel can be made from pig iron and ore with a consumption of not more than 850 kw-hr. per ton, starting with a cold charge. This decarbonizing process is also suitable for removing a certain amount of phosphorus from the pig iron, thereby improving the resulting steel. The phosphorus is, of course, removed only at the end of the melting, when the percentage of carbon hase been sufficiently reduced, i.e., to 0.10 per cent or less.

If using high-grade pig iron the process may be stopped as soon as the carbon is reduced sufficiently to meet the specification for the castings. Naturally the decarbonizing can be interrupted by pouring off part of the charge at, say, 0.60 per cent C and then adding more iron ore to reduce the carbon to 0.20 per cent or less, if extra soft castings are required. This operation is performed with ease permitting the steelmaker to take all the time he wants for testing his steel in any way desired.

### No "Hit or Miss" Method

The electric steel furnace makes it possible to turn out heats of steel of practically exact chemical composition. The carbon may be lowered or increased at will and additions may be made for making various kinds of alloyed steel. The quantities which in each case should be added to obtain a certain specified percentage of nickel, chromium, vanadium, etc., can be closely calculated. Sulphur and phosphorus may be reduced to practically nil if desired by simply "working" the charge with a sufficient number of refining (basic) slags, melting them one after the other, carefully removing each preceding slag before adding a new one.

The limit for this refining is only the consideration of cost. The consumption of energy and time will, of course, increase if very low-grade materials are to be converted into high-priced tool steel. The fact that a remarkable degree of refining is possible in the electric furnace is well known, quoting, for instance, Mr. E. F. Lake (*Iron Age*, March 27, 1913). In his article on "European electric steel castings" this author makes the statement that "for various reasons high-grade steel castings can not be made with the open-hearth process," and he adds "the Bessemer process need not be mentioned, as it is well known to be less adapted to such work than the open-hearth and only *applicable to very cheap castings*." Speaking about the small converter which is a close development of the Bessemer furnace, Mr. Lake states that "this process has its limitations, however, and it is best adapted to medium grades of steel castings. The extra-fine grades require the crucible or electric furnace process for melting and refining."

The conclusion to be drawn from this is that it is certainly advisable for any steel foundry of importance to make arrangements for a suitable electric furnace in its plant. Only if this is done can the customers be assured of strictly high-grade steel, when such is required. And this is going to be frequently demanded in the future when designers and builders of machinery know that such high-grade steel castings are obtainable at short notice and at reasonable cost.

The proper course for a steel foundry would be at first to erect a furnace of medium size, say, 1 to 1½ tons capacity, to work together with the converter or whatever melting furnace may be in use. The most difficult and expensive castings could then be taken care of by the electric furnace leaving it to the converter or open-hearth to produce the lower and cheaper grades of work. This would be a natural development, greatly facilitating the more general introduction of higher grades of castings by means of this new melting tool.

### Capacity of the Electric Furnace

The electric furnace when used to melt cold steel scrap is to be considered especially as a refining furnace intended more to produce quality than quantity. The time for finishing a heat depends not only on what quality of steel is wanted but also on the power available. It is possible to overload an electric furnace thereby obtaining quick melting and increased output, but if persisted in this, of course, will injure the lining of the furnace and increase the cost of maintenance. This is the case also with the converter, if it is used for a very forced work such as melting 6 tons of steel in one hour in a 2-ton converter.

Should it really be required to accumulate 4 to 6 tons of steel having available only a 2-ton electric furnace, this might be done by overheating the first and second charge considerably and pouring them in a properly designed and thoroughly preheated mixer. By properly lining the mixer it is possible to avoid loss of heat, causing the steel to cool off only very slowly.

The electric steel may therefore be kept hot for several hours without getting below the casting temperature. The steel in such a mixer may, of course, be kept hot also by means of an oil- or gasburner or by introducing a few pounds of thermit ($Al + Fe_2O_3$) which generates a very large quantity of heat, when the finely powdered aluminium is brought to react and combine with the oxygen in the iron ore. This method, of course, involves an extra cost per ton of steel, but circumstances may justify such an occasional expense.

The Tropenas converter is always lined with acid brick. These do not stand a higher temperature than about 1650° C., the fusing point of brick being at 1700 to 1750°. Ordinary soft steel congeals at about 1450° and it is consequently not possible to overheat the steel more than 200° without spoiling the lining of the converter. The electric furnace again, if lined entirely with basic materials permits maintaining the temperature at about 2150° C. or 500° higher than is possible in the converter. The electric steel, therefore, may be poured into the basic-lined receiver at a temperature which is some 700° C. above the melting point of the steel. The electric furnace is the only one in which it is possible to produce really superheated steel of first-class quality.

### Segregation

It certainly is a remarkable statement of Mr. Muntz that the electric furnace produces greater segregation than the Tropenas converter. The consensus of opinion of leading authorities is the opposite. Without doubt the electric furnace is very much effective compared to other melting tools in preventing segregation.

Mr. W. R. Walker read before the American Iron and Steel Institute, May, 1912, a paper on "the electric furnace as a possible means of producing an improved quality of steel," in which he states that ingots of even 8 tons have been produced electrically which are "practically free from segregation."

### Wide Market for Electric Steel Castings

Quite contrary to the concluding statement by Mr. Muntz that the electric steel does not find a ready market is the fact that there is a wide demand for just such high-grade steel castings as can only be produced from the electric furnace. The machinery trade is constantly raising the standard specifications whenever there is the slightest chance that public safety would be endangered on account of low-grade steel being employed for important details. Builders of automobiles, locomotives, airships, elevators, carriages, street and railway cars, etc., all recognize the importance of specifying the best quality of steel obtainable at reasonable cost.

This is a well established practice in both Europe and America. The writer is in a position to testify to this, because of his connection with certain interests devoted to the economical and practical development of one of the most promising of the electric steel furnaces now in the market. The amount of inquiries for electric furnaces coming in from all parts of the world, and especially from the United States, is astonishing and is a sure indication of the future electric steel melting. People are beginning to realize that the electric furnace has come to stay, but that it is by no means "foolproof." It is quite possible to spoil steel in several ways and it must not be expected that any person not familiar with steel generally should be able to use the electric furnace to best advantage. If, however, the quality of the steel in any charge is not satisfactory, it is in most cases possible to correct this by making proper additions to the bath, keeping it long enough to obtain exactly the steel which is wanted.

If handled with reasonable care and intelligence the electric furnace is really a most useful and easily managed melting apparatus, certain to play an important role in the future development not only of the steel casting industry but in the whole art of iron and steel making.

Aktiebolaget Elektriska Ugnar,
Stockholm, Sweden.

## Goslar Convention of the Association of German Metallurgists

The annual meeting of the Association of German (non-ferrous) Metallurgists and Mining Men (Gesellschaft Deutscher Metallhütten- und Bergleute) was held from July 3 to 6, 1914, in Goslar in the Hartz Mountains.

After various visits to mines and metallurgical plants in the neighborhood the meeting was opened on the evening of Friday, July 3, by a speech of the president of the association, Mine Director **Niedner**, of Tarnowitz, in Upper Silesia.

Bergrat **Wolff** then lectured on some of the geological and technical problems of the Rammelsberg mine.

On Saturday, July 4, various other industrial plants were visited and an excursion was made to Hartzburg. In the evening a social meeting was held at which two American engineers, **H. N. Stronck** and **J. F. Boyle**, lectured on scientific management in mining and metallurgy. The subject of their discussion was the problem how with higher wages it is possible to reduce the cost of operation in mining and metallurgy on the basis of the principles of scientific management.

The business meeting was held on Sunday, July 5. Bergrat **Volgelsang**, of Eisleben, was in the chair. The membership is now more than 800. The organ of the society is the journal "*Metall und Erz.*" A special section has been formed for zinc metallurgy, and at the first meeting of this section Director **Holey**, of Duisburg, had lectured on the roasting of zinc blende.

Papers were then presented by Professor **Krusch** on possible platinum deposits in Germany and by Director **Juretzka**, of Breslau, on the metallurgy of zinc. The author pointed out that on account of the rise of the price of lead and zinc various new processes have been introduced into practice. He discussed recent improvements in the manufacture of retorts and in the drying of the retorts and gave the results of experiments on the winning of zinc in vertical retorts. He also discussed the problem of zinc smelting in shaft furnaces.

Finally Mr. **Bueler de Florin**, of Aussig, read a paper on the use of nitric acid for the leaching of ores, giving a review of various processes which have been proposed in this field. Kingsley and Rankin have proposed to let nitric acid react with sulphide ores, especially lead sulphide. Kingsley intends to produce a lead nitride solution. Rankin intends the formation of lead sulphate which is possible with the use of concentrated acid at a raised temperature with stirring and the application of two atmospheres pressure. The Norsk Hydro-Elektrisk Kvaelstoffaktieselskab has proposed a treatment of ores containing bismuth as sulphide or oxide in small quantities. The author has proposed leaching copper oxide or carbonate ores rich in lime and free from sulphur with diluted nitric acid.

In all four processes the regeneration of the acid forms an important step. How this is carried out in the four processes is shown in the following equations:

*Kingsley:*

Treatment of ore:

$$3PbS + 8HNO_3 = 3Pb(NO_3)_2 + 2NO + 4H_2O + 3S$$

Regeneration of acid:

$$Pb(NO_3)_2 + Na_2CO_3 = PbCO_3 + 2NaNO_3$$

$$2NaNO_3 + H_2SO_4 = Na_2SO_4 + 2HNO_3$$

*Rankin:*

Treatment of ore:

$$3PbS + 8HNO_3 = 3PbSO_4 + 8NO + 4H_2O$$

Regeneration of acid:

$$2NO + 3O + H_2O = 2HNO_3$$

*Norsk Hydro-Elektrisk Kvaelstoffaktieselbskab:*

Treatment of ore:

$$Bi_2O_3 + 6HNO_3 = 2Bi(NO_3)_3 + 2H_2O$$

Regeneration of acid:

$$Bi(NO_3)_3 + H_2O = BiONO_3 + 2HNO_3$$

Büeler:

Treatment of ore:

$$CuCO_3 + 2HNO_3 = Cu\ (NO_3)_2 + H_2O + CO_2$$

Regeneration of acid:

$$Cu\ (NO_3)_2 = CuO + N_2O_5$$

$$N_2O_5 + H_2O = 2HNO_3$$

The treatment of ores with nitric acid is, however, sensible only if the nature of the ores or the local conditions exclude the use of other methods. After the close of the meeting a banquet was held and on Monday, July 6, a visit was paid to the Rammelsberg mine.

---

## Some Economic Aspects of Industrial Chemistry*

BY DR. BERNARD C. HESSE

In considering this subject the difficulty lies not in a scarcity of material, but principally in keeping the discussion of the voluminous matter within a small compass.

Taking the thirteenth census of the United States as a guide in ascertaining what is regarded by the Census as industrial chemistry, it will be found that in the division of chemical and allied products, metals and all metallurgical operations are excluded, as well as the production of refined petroleum, and a host of other large industries such as glass, soap, pottery, sugar, starch and the fermentation industries which depend upon chemical reactions and chemical control for their successful execution.

The Census of the United States includes under chemicals and allied products nine principal divisions:

1—Paint and varnish.
2—Chemicals.
3—Fertilizers.
4—Explosives.
5—Dyestuffs and extracts.
6—Sulfuric, nitric and mixed acids.
7—Wood distillation (not including rosin and turpentine).
8—Essential oils.
9—Bone, carbon and lampblack.

For the present, these nine divisions of the Census will be considered. Having arrived at a tentative conclusion as to the scope of the subject matter, this subject matter will be considered from the two following aspects:

I—The relationship of these industries to the manufacturing industry of the United States as a whole.

II—The position of the United States in those respects as a buying and selling nation.

The volume and distribution of foreign trade of the United States in the fiscal year of 1913 is given by the Department of Commerce as follows:

| | |
|---|---|
| Exports | $2,428,506,358 |
| Imports | 1,812,978,234 |
| Total | 4,241,484,592 |
| Excess of exports | 615,528,124 |

In order to obtain a conception of the relationship of these nine branches of chemical industry to the manufacturing industries of the United States as a whole, Table I will be helpful.

The story told by Column D is encouraging in some respects, and is not so encouraging in others. Compared with other manufacturing industries, the chemical and allied industries do not so easily lend themselves to small units. It takes 3.3 times as much capital for the average chemical plant as for the average manufacturing plant. This is the discouraging feature from the individual point of view.

From the broader point of view, Column D, however, is very encouraging. The average chemical plant requires 50 per cent. more help than the average manufacturing plant; it employs over two and a half times as many salaried employees as does the average manufacturing plant, but unfortunately only 34 per cent. more than the average number of wage-earners. The average chemical plant bears much more than its proportionate share of expenses, whether in the shape of salaries, wages, materials, or miscellaneous expenditures; in the value of the product produced per unit of chemical plant the average chemical plant produces 161 per cent. more than its average share.

If the principal object of manufacture be the enhancement of value of the outgoing material over the incoming material, then the fact that the average chemical plant enhances its raw material 148 per cent. more than its average share is a matter for congratulation and of encouragement.

Turning now to the question of productive power of capital invested in chemical industry, it will be found on inspecting Column E that a dollar is not so productive in the chemical and allied industries, average against average, as in the other branches of manufacturing endeavor. The disbursements for salaries, materials, power, value of product and expenses of miscellaneous nature are each about three-quarters of the average of the same items for the other branches of manufacture, and the enhancement in value is only 75 per cent. of the average enhancement produced by unit capital investment in the other branches of manufacture. The dollar so invested employs fewer wage earners, salaried or otherwise, than a dollar otherwise invested in manufacturing enterprise. This, of course, is merely a natural consequence of the high initial cost of plant, the large size unit of plant required and the close markets.

Turning to the value of products in Column B, it is to be noted that the percentage participation of each of the nine divisions in that title is as follows:

| | | | |
|---|---|---|---|
| Paint and varnish | 29.4 | Sulfuric, nitric and mixed acids | 2.3 |
| Chemicals | 27.4 | Wood distillation | 2.3 |
| Fertilizers | 24.5 | Essential oils | 0.3 |
| Explosives | 9.4 | Bone, carbon and lampblack | 0.4 |
| Dyestuffs and extracts | 3.8 | | |

The thirteenth census of the United States has distributed the participation of these nine divisions in this amount of product with considerable detail, which does not lend itself very well to discussion. The not specifically described items amount to $73,563,059, or 17 per cent. of the total. For the purpose of obtaining a better understanding of the relationship of the various principal items under each of these nine divisions, Table II has been prepared.

Within the nine divisions given, the United States is in a large measure self-sustaining, although it is necessary for it to obtain much of the raw material from abroad. In the division of dyestuffs and extracts, and particularly that portion of it dealing with artificial dyestuffs, it is to be noted that during 1913, the total importation into the United States of artificial dyestuffs, exclusive of alizarine dyes and indigo, amounted to $7,105,284; during the census year of 1910 this country manufactured $3,462,436 worth of such artificial dyestuffs which amounts roughly to 32 per cent. of this country's entire consumption of the so-called coal-tar dyes; no doubt, since the census year 1910, the domestic production of coal-tar dyes has increased. However, much of the coal-tar raw material used in such manufacture comes to us from abroad, particularly from Germany and England.

In the fertilizer division we are, of course, dependent for our potash requirements, upon Germany, and these

---

| Gunpowder | 1,736,427 | 4.3 |
| Other explosives | 3,913,787 | 9.7 |
| Materials not elsewhere specified | 2,155,793 | 5.4 |
| Total | 40,139,661 | |

| Dyestuffs and Extracts | Value in Dollars | Percentage of Total Division |
|---|---|---|
| Artificial dyestuffs | 3,462,436 | 21.6 |
| Extracts for dyeing | 991,974 | 6.2 |
| Extracts for tanning | 6,449,105 | 40.4 |
| Other tanning materials | 625,401 | 4.0 |
| Mordants | 99,797 | 0.6 |
| Sizes and finishes | 2,418,652 | 15.0 |
| Ground and chipped woods, etc. | 344,761 | 2.2 |
| All other products | 1,562,448 | 9.7 |
| Total | 15,954,574 | |
| SULFURIC, NITRIC AND MIXED ACIDS | | |
| Sulphuric acid | 5,629,496 | 57.0 |
| Nitric acid | 499,303 | 5.1 |
| Mixed acid | 1,438,475 | 14.6 |
| All other products | 2,316,783 | 23.5 |
| Total | 9,884,057 | |
| WOOD DISTILLATION (not including rosin and turpentine) | | |
| Wood alcohol: | | |
| Crude | 1,627,878 | 16.7 |
| Refined | 2,901,709 | 29.8 |
| Acetate of lime | 1,981,220 | 20.3 |
| Charcoal | 2,351,644 | 24.0 |
| Turpentine | 249,526 | 2.6 |
| All other wood distillation products | 357,290 | 3.7 |
| All other products | 267,731 | 2.8 |
| Total | 9,736,998 | |
| BONE, CARBON AND LAMPBLACK | | |
| Bone black | 1,070,333 | 50.0 |
| Carbon black | 625,514 | 29.3 |
| Lampblack | 439,707 | 20.6 |
| Total | 2,135,554 | |
| ESSENTIAL OILS | | |
| Oil, peppermint | 519,079 | 29.8 |
| Oil, black birch | 102,045 | 5.9 |
| Oil, spearmint | 83,283 | 4.8 |
| Oil, wintergreen | 68,983 | 3.9 |
| Other oils | 335,213 | 19.3 |
| Witch-hazel extract | 412,322 | 23.7 |
| All other products | 216,309 | 12.4 |
| Total | 1,737,234 | |

amount in round numbers to $1,000,000 per month. In the same division we are dependent upon Europe for much of the ammonia entering into the fertilizers, amounting in 1910 to over $4,000,000. It will probably not be long before most of our ammonia requirement is supplied by our own by-product coke-ovens.

## Industrial Chemistry in Its Broad Aspect

However, industrial chemistry or chemical industry is much broader in scope than is indicated in the thirteenth Census of the United States on chemicals and allied products. From the point of view of the person with chemical training, every industrial operation which calls for chemical control is a branch of industrial chemistry or of chemical industry, the two terms being used interchangeably.

In Germany the official classification of material connected with chemical industry is as follows: 1—Malt, oil, fruits, plants, etc. 2—Industrial or medicinal vegetable products. 3—Tanning extracts. 4—Resins, gums and adhesives. 5—Caoutchouc and camphor. 6—Animal and vegetable fats and oils. 7—Animal products. 8—Starch and sugar. 9—Alcohol, acetic acid, mineral waters. 10—Mineral and fossil raw materials. 11—Ores, iron and slags. 12—Fossil fuels. 13—Mineral oils and like fossil raw materials. 14—Coal-tar oils and products. 15—Waxes. 16—Soap and fat products. 17—Chemical and pharmaceutical products. 18—Miscellaneous chemical and pharmaceutical products. 19—Dyes and dye materials. 20—Ethers and alcohols. 21—Volatile oils, synthetic perfumes, toilet articles. 22—Artificial fertilizers. 23—Explosives and combustibles. 24—Wood fiber and chemical paper. 25—Metals.

These twenty-five large classes or divisions comprise four hundred and forty-two sub-classes.

An examination of the records of imports and exports into and from the United States during the fiscal year 1913, discloses a total business of $4,241,484,592; of this, not less than $1,302,274,994 or 30 per cent. deal with products of chemical industry or materials used in the products of chemical industry, and of these $759,193,688, or 18 per cent. of the total represents imports and $543,081,306, or 12 per cent. of the total represents exports leaving a balance of trade against the United States, $216,112,382.

LARGE ITEMS IN CHEMICAL TRADE OF THE U. S. FOR 1913.

| | |
|---|---|
| IMPORTS | |
| Sugar | $204,212,581 |
| Hides and skins | 117,386,174 |
| Unmanufactured India rubber | 101,333,158 |
| Paper and paperstock | 27,706,697 |
| Potash compounds | 14,408,124 |
| | $465,046,734 |
| EXPORTS | |
| Refined petroleum and its products | $139,882,905 |
| Copper as metal | 120,605,914 |
| Beef and hog products | 82,890,777 |
| Leather | 42,384,199 |
| Naval stores | 26,471,492 |
| Fertilizer material | 11,400,888 |
| Cement industry | 5,822,107 |
| | $429,458,282 |

Information as to the distribution of the exports and imports just given as to countries of destination and countries of origin is not readily assessible, since it would be a never ending task for the officials of the Department of Commerce to rearrange all of this vast information from the various points of view possible.

### Movement of Chemical Products Between Germany and the United States

However, fragmentary information is accessible with respect to the relationship between the United States and Germany as regards the interchange of chemical products between the two countries. This information is based upon German official publications.

From the point of view of values, information is at hand for only the year 1904. In that year Germany sent to the United States $16,993,200 worth, and the United States sent to Germany during that time $38,194,240, or an excess in favor of the United States of $21,201,040, which means about $1,800,000 per month.

With regard to the tonnage movement between those two countries, information for the year 1913 is at hand, and it shows that during that period a total of 3,430,564 metric tons of commodities of the chemical industry passed between the two countries, of which 1,917,430 metric tons passed from the United States to Germany, and 1,513,134 metric tons passed from Germany into the United States; that is, the United States sent to Germany an excess of 404,000 tons over what it took from Germany in 1913.

### Freight Movements in the United States

In 1911 the total freight movement over the railroads of the United States amounted to 967,233,991 tons; of these about 14 per cent. comprised manufactured goods, and about 28,000,000 tons of the total freight moved was composed of products of chemical industry, that is, about 3 per cent of the total freight movement of this country is represented by products of chemical industry. The three and a half million tons gross above referred to between the United States and Germany, therefore, represent about 12 per cent. of the probable total freight movement of products of chemical industry in this country.

### Efficiency of American Industrial Chemistry

An examination of the relative exports and imports of products of chemical industry from and into the United States shows that there is little, if any, ground for criticism of American chemists in not utilizing their opportunities. It is safe to say that the American chemical industry is developing its own natural resources with a degree of foresight and success very favorably comparable with that accomplished by chemists in other lands. Much is heard in criticism of American chemists for not developing a coal-tar chemical industry, but I do not believe such criticism to warrant a wholesale belief in the backwardness of American chemists. There can be no question that the chemical work involved as well as the engineering work involved in the production of a useful and usable illuminating oil, or a medicinal preparation from crude petroleum, compares very favorabily with the chemistry involved and the engineering involved, in the production of the majority of so-called coal-tar dyes. The relative economic value of the two products is, of course, in favor of the products of petroleum.

It will be sufficient to say Germany is supreme in the coal-tar dye industry, because (1) Germany was the home of the industry; (2) the industry itself is so dependent upon interlocking chemicals and the growth of this interlocking dependence has been as fast as economic development warrants and has now reached such a stage of complexity and interdependence that it is difficult of transplantation as a whole; (3) there are relatively few so-called staple articles among the coal-tar dyes—by staple is meant those which are consumed in quantities to be measured by tons—many of those few are so interlocked with subsidiary or by-products that the transplantation of the work out of Germany would be economically unprofitable.

Wherever it has been profitably transplantable to this country, the manufacturing of such staples has been done, and with considerable success even though the raw material supply is still provided by Europe.

### Theory and Practice

The chemical industry, probably more than any other industry, is dependent upon the application of much theoretical work, i. e., scientific work to every-day conditions, and in order that the chemical industry may grow, it is necessary that there should be brought to bear upon the manufacture of each and all of the products the highest chemical training available under the circumstances. The beneficial interaction of practice upon theory and theory upon practice, is evident in almost every branch of industrial chemistry. It has been brought to its highest efficiency, however, in the organic division and more particularly that dealing with coal-tar dyes and synthetic medicinals and pharmaceuticals. However, the chemist can, with profit follow Mr. Kerr's excellent advice to engineers when a difficulty is encountered: "Go as far as you can see and then see how far you can go."

The simplification brought about in organic chemistry through the creation of the Kekulé conception of the structure of benzol, made the development of the coal-tar dye industry in its early stages possible, or at any rate immeasurably facilitated it. In return, the coal-tar dye industry has enriched scientific or theoretical organic chemistry with a wealth of information and facts with respect, not only to benzol, but to naphthalene, anthracene and the higher aromatic hydrocarbons; the two working together have developed a very large number of new classes of organic compounds, for example: the azines, oxazines, numerous classes of azo compounds and the wealth of oxy and oxyamido derivatives in all the classes. New methods of sulfonation, chlorination and nitration have been developed almost without number, and in turn, theoretical organic chemistry has supplied the industry with many useful methods of the same kind.

To contemplate the results of this interaction is to view one of the greatest of intellectual triumphs. It is this very fact that has misled so many to ascribe to the coal-tar dye industry an economic effect far beyond its actual and to belittle the economic effect of the so-called inorganic industry. It is perfectly safe to say that the money value of the inorganic exceeds the money value of the dye industry by at least 15 to 1.

From 1877 down to the close of 1912 there were taken out in Germany 5,675 German patents, or 158 per year, dealing with the utilization of coal-tar hydrocarbons and their by-products; it has been estimated that not more than one out of every hundred has secured financial returns for its owners. During the years 1895 to 1903, 382 German patents, or at the rate of 48 per year, were taken out in the inorganic chemical industries.

It would be an interesting subject for speculation to consider the intellectual effort involved in the 5,675 coal-tar patents as compared with the intellectual effort required for the 382 inorganic patents. It would also be of interest to consider the difficulties, financial and otherwise, in the way of creating those respective patents. A far-reaching experiment can be made in the coal-tar industry for a very little expenditure of material and labor, but in the inorganic industry the expenditure of material and labor is inordinately greater. You can make a coal-tar dyestuff and determine whether there are any probabilities of its having commercial utility at an infinitely slighter expense than you can determine whether certain alterations in the construction of a bleach-chamber in the production of bleaching powder will or will not be profitable; on the other hand, as you approach the more highly developed and almost completed manufacturing phase of coal-tar dye chemistry, you immediately come into about the same difficulties and embarrassments that you do in the inorganic field, and for precisely the same reason, namely, that in both cases you are endeavoring to develop refinements, and refinements are much more difficult of detection, elaboration and application than is the question of determining whether you have, or have not, a new and probably useful dyestuff.

By way of illustration, there are probably fewer than 35,000 compounds listed in Beilstein, but it will be no difficulty whatever to find a dozen different patents on coal-tar dyes, each and every one of which covers several million, even several hundreds of millions of different and distinct dyestuffs. Of course, to discover a new type of a dyestuff is almost as difficult as it is to discover a refinement in the almost fully developed inorganic industry, but once the type is given, there is no difficulty in creating a new dyestuff under that type.

### The Function of the Chemist as an Individual

Now, the function of the chemist in the production of things is twofold. Take the apparently most humble position, namely, that of analyst. Upon his accuracy of manipulation depends, in a large measure, the profitableness of the undertaking. If an analyst makes a mistake of 1 per cent. in determining copper, on the $120,000,000 worth that we export annually, that would mean a loss of $100,000 per month. Therefore, analytical control, in order to be of value, must be accurate, since inaccuracies can easily run into large sums of money.

But the chemist's contribution does not stop merely with control; he does create a great many new uses for old things, and he does create new things and find uses for them. To be able to do these things to the best advantage, he must be thoroughly versed in what has been done, must know what tools are at his command, must be able to use those tools and to tell when they shall be used, must possess also the merchant's instinct of values, if he desires to rise to the highest efficiency in industrial chemistry. Of course, he must know how to handle men, and how to get results with what is at his command, as must anyone who attempts to conduct any business enterprise.

He must be alert, and he must overcome any disdain that he may naturally have for small things, for in industrial chemistry, perhaps oftener than in any other, it is the small thing that has pointed the way to achievement and success.

It is an old story how the production of benzol from coal gas was brought about by a mistaken notion that oxalic acid could be made from coal gas and nitric acid. An alert and very observant chemist in repeating this attempted synthesis found not only that oxalic acid was not formed, but that nitrobenzol was produced with benzol dissolved therein. That was the beginning of the recovery of benzol from coal gas, and the addition to the sources of benzol of a source much greater and more dependable than any theretofore available.

The neglect of a laboratory boy to maintain the temperature he was directed to keep in a certain vessel, taught that laboratory boy nothing, but the chemist in charge following up this result, finally ended up with a method of substituting sulfuric acid for bromine, thereby reducing the cost of production by over 50 per cent. In both of these cases it is very doubtful if a man having no training beyond that required in the production of the things with which he was directly concerned, would ever have made those discoveries. The attempt to make oxalic acid would have resulted in failure, and would have been so reported, the result of the laboratory boy's negligence would have been dumped into the sewer, and a new start made along the original lines.

### Conclusion

I have shown how, in a national sense, the chemical industry contributes a very substantial portion to our national welfare and the useful part it plays in this work-a-day world, in the employment of persons, materials and of capital; how in a broader sense it touches almost every field of human activity; how it is interwoven with the means required for the gratification of all our personal needs and desires.

It needs merely to be mentioned in order to bring about a full appreciation of the importance of the chemical industry to refer to the important part it plays with respect to agricultural chemistry. The chemical methods of investigation and research applied to agricultural problems indicate the requirement of certain materials by the soil, and these materials are supplied by the chemical industry. In that way the chemical industry contributes to the activity of the soil and the increased output per unit area of agricultural products.

Conversely, as in the case of alizarin and indigo, hundreds upon hundreds of square miles of the earth's surface were devoted to the cultivation of the plants necessary to produce these articles. This very large area is no longer required for that purpose, and it is safe to say that in the chemical factories now producing these things the combined working area is under four square miles. Right or wrong, I have always personally felt that had the botanist devoted the necessary attention to the growth and cultivation of indigo plant when the first synthesis of indigo was announced in 1880, the displacement of vegetable indigo between 1897 and 1900 by synthetic indigo would not have taken place, or at any rate, it would not have been accomplished after so brief a struggle. The botanist has assisted wonderfully in increasing the alkaloidal content of cinchona barks, and in the discovery of a large number of new plants capable of producing a latex suitable for India rubber production and he has also contributed greatly to the development of plantations, wherein the yield per unit area is much increased.

While at the present day it may not be commercially profitable to produce synthetic rubber, or synthetic camphor, or synthetic nitric acid, or synthetic ammonia, yet it is perfectly true that the very existence of these possible synthetic sources of these materials renders it less and less likely that there will be any undue advance in the cost to the consumer of these articles; at any rate, the cost will not be advanced beyond a figure where the synthetic process can achieve a reasonable profit.

Chemical industry, therefore, not only provides for our present needs, but acts as safety device against famine, shortage or undue monopolization of a number of vegetable and mineral products.

## Features in Work of Bureau of Standards

Secretary of Commerce Redfield has just received a report from the director of the Bureau of Standards relative to the work of that bureau which shows how many interesting features there are in the varied and extensive work of testing and investigation being conducted by that bureau.

For some time the bureau has been working on *safety rules* to be observed in the operation and maintenance of electric generating stations and substations, and on the overhead and underground distributing wires in connection therewith, and a set of rules has been prepared for publication by the bureau.

The report on mitigation of *electrolysis damage* in Elyria, Ohio, has beeen completed and was presented to the city, the gas company, the telephone company and the railway company some weeks ago and accepted by all the interests involved. The railway company has promised to do everything recommended by the bureau, which will result not only in correcting very serious electrolysis troubles but also will improve the street-railway service in Elyria and vicinity, improve the lighting of the cars and save enough money to the railway company to justify fully the total expense involved apart from the consideration of electrolysis mitigation. This is to be accomplished by a rearrangement of their distribution system and the installation of negative cables for the return of street railway current to the power stations. Because of these economies the railway company is willing to undertake the expense of new construction and new arrangement without recourse to city ordinances or pressure from the courts.

In the *cement laboratory* in Washington tests were made from samples for delivery of about six thousand barrels. At the Northampton laboratory the June shipments sampled and tested represented 66,700 barrels of cement, an average daily rate of 2565. It is interesting to note in this connection that the total shipments tested at this laboratory now aggregate 6,158,108 barrels, mainly for the Panama Canal.

About two months ago an instrument was constructed for the United States Weather Bureau for measuring the so-called *nocturnal radiation*, which usually is a loss of heat from terrestrial substances into space. The latest report shows that this instrument is unusually sensitive and that it meets all the requirements.

The influence of atmospheric conditions on the *testing of sugars* has long been an unknown quantity owing to the difficulty of controlling both temperature and humidity in the research laboratory. Relatively large and inexplicable differences have been noted for some years between the tests on imported sugars for the collection of duty at the various ports of entry. So great have been these differeces that sugars have purposely been imported via certain ports with the intent of paying a lower rate of duty. The bureau has studied this question, and its investigation now shows not only the exact cause of differences but also a simple and certain method of eliminating them.

One of the interesting and important pieces of work has been the establishment of a *standard of radiation* of which not merely the light in a visible spectrum was measured but the total radiation visible and invisible was accurately determined. These determinations have been completed with four radiometers and show most excellent agreement as to results, within 0.5 per cent compared with the previous calibration of these lamps. Hence the standard of radiation as defined by these laamps may be considered well established. This standard is quite distinct from standards of light.

## Program of Chicago Meeting of the American Institute of Metals

The eighth annual meeting of the American Institute of Metals will be held in Chicago from Sept. 7 to 11 (Monday to Friday).

Monday, Sept. 7: Registration La Salle Hotel.

Tuesday, Sept. 8, 10 a. m.: Joint meeting with the American Foundrymen's Association, Hotel La Salle. Subject: "Safety Work."

Safety and Foundry operations, address by M. W. Alexander, General Electric Company, West Lynn, Mass.
Safety First, by F. W. Reidenbach.
Progress in the Safety First Movement, by Arthur T. Morey.
Safety in Connection with Grinding Wheel Operations, R. G. Williams.
Safety in Sanitation, by A. W. Gregg.
Safety First—Driving Back the Saloon, by Thomas D. West.

Tuesday, 2 p. m., Hotel La Salle: General papers and reports.

Report of Official Chemist, by Arthur D. Little, Inc.
Progress in the Nomenclature of Alloys, by G. K. Burgess.
Some Recent Applications of Metallic Cobalt, D. B. Browne
Drop Pouring Process of Casting, by E. A. Barnes.
Bull Run Tale, by Jesse L. Jones.
Modern Die-Casting Practice, by Charles Pack.
Die Cast Aluminum, by A. B. Norton.
Non-ferrous Alloys for Automobile Construction, E. B. Horne.

Wednesday, Sept. 9, 10 a. m.: Saddle and Sirloin Club, Stock Yards. Cost Congress. Joint session with A. F. A.

Foundry Cost Keeping, by F. J. Stevenson.
Efficiency in Foundry Operations, the Essential Factor in Reducing Production Costs, by A. K. Hathaway.
Efficiency in Foundry Work, by F. A. Parkhurst.
Revision of the A. F. A. Standard Foundry Cost System, by Harrington Emerson.
Practice in Estimating Selling Price of Castings, by A. O. Backert.

Wednesday, 2 p. m.: Rolling Mills; Physical and Chemical Testing.

Care and Conversion of Rolling Mill Scrap, by W. W. Rogers.
A Brief Visit to a Rolling Mill, by Edward J. Gutsche.
A Hot Shortness Testing Machine for Aluminium Alloys, by A. B. Norton.
Making Aluminium Test-Specimens on Castings, by A. B. Norton.
Standard Test Bars of the Zinc and Bronze, Copper 88, Tin 10, Zinc 2, by C. P. Karr.
A New Method for the Determination of Zinc in Alloys, by G. E. Lundell and Mal Kim Bee.
Brinnell Hardness Testing of Non-Ferrous Alloys, V. Skillman

Thursday, Sept. 10, 10 a. m.: Saddle and Sirloin Club, Metallurgy and Metallograph.

Commercial Classification of Copper, by Lawrence Addicks
Spelter Manufacture and Properties, by George C. Stone.
Metallurgy of Tin and Antimony, by W. A. Cowan.
Ternary Alloys of Copper, Tin and Zinc, by S. L. Hoyt.
The Effect of Repeated Remelting on Copper, by F. O. Clements.

Thursday, 2 p. m.: Melting Practice.

Tests of Electric Furnaces for Brass Foundry, Herbert G Dorsey.
Electric Furnace for Medium Temperatures, by E. M. Schmelze
Electric Brass Melting from the Central Station Viewpoint, by H. M. St. John.

Friday, Sept. 11, 10 a. m.: Saddle and Sirloin Club.

Melting Losses in Electric Brass Furnaces, by H. W. Gillett and J. M. Lohr.
Use of Producer Gas in Melting Yellow Brass, by E. H. Guenther
Test of Natural Gas Fired Furnaces under Factory Conditions, by Fred L. Wolf and Robert B. Burr.
Electric Brass Melting, by G. H. Clamer and Carl Hering.
Pyrometers for Melting Brass and Bronze, by H. W. Gillett

# Utah Meeting of American Institute of Mining Engineers

The Utah meeting of the American Institute of Mining Engineers proved after all a tremendous success, featured by cordial hospitality, elaborate entertainment, and excellent technical sessions, in which metallurgical papers predominated. Owing to the somewhat unsettled conditions of the Western mining field, there had been a doubt whether it would not be better to postpone the meeting, and recommendations to that effect had been made by Utah and Colorado members. But cooler council fortunately prevailed and the meeting was held exactly according to the program in almost every point. The only notable omission was the trip on Tuesday to the Arthur concentrating mill, which had been closed down.

The attendance was large and high-class. The registration list showed 340 names.

After an organ recital at the Mormon Tabernacle in the afternoon of Monday, Aug. 10, and an automobile trip through Salt Lake City, the meeting was officially opened on Monday night in the ballroom of the Hotel Utah by President B. B. THAYER.

D. C. JACKLING welcomed the society to Salt Lake City and reviewed the mining and metallurgical developments in Utah and the contributions of Utah engineers to progress in the industry.

The subject of the technical session which followed and in which R. C. GEMMEL presided was a symposium on copper leaching, papers being presented by Messrs. Laist and Aldrich, Laist and Frick, Austin, Croasdale, Laist and Wiggin, Holt.

## Copper Leaching

### Leaching at Anaconda

The paper by **Frederick Laist** and **Harold W. Aldrich** discusses "Experimental Leaching at Anaconda." The object of the construction and operation of the 80-ton leaching plant was to test out the leaching of sand tailings on a large scale and, if possible, determine a definite method of operation, and the best construction for the larger unit which is now being built. It was also of importance to obtain some practical data as regards cost items.

The 80-ton plant was not expected to be a commercial success. A leaching process on such low-grade material necessitates the treatment of a very large tonnage. Such a cost item as labor, for instance, is entirely out of proportion in such a small plant. The amounts of acid, salt, scrap iron, and fuel for roasting, however, are the same per ton in an 80-ton plant as in a 2000-ton plant. These costs were definitely established. Also the percentages of extraction and grade of tailings were definitely determined for a large-sized unit.

The equipment of the plant and the gradual changes which were made in equipment and method of operation are described in great detail in the paper. Originally the six-hearth MacDougall roaster was designed for oxychloride roasting and salt was added on the fourth floor. After a 50-day successful run it was decided to discontinue the feeding of salt into the furnace and see what results could be obtained. This method offered many advantages. No valuable metals were volatilized and no accretions formed in the furnace to cause trouble. The extraction on the copper was even better than on the chloridizing roast, but the silver recovery was not so good.

For the detailed results of the tests the reader must be referred to the complete paper (*Bulletin* Amer. Inst. Min. Eng., August, 1914, p. 2165). It must suffice here to give the chief general results:

The feed from the mill averages between 0.65 and 0.70 per cent. copper, about 5 per cent. moisture, and about 3 per cent. sulphur. Ninety tons per 24 hr. of this feed can be roasted in a 20-ft. MacDougall furnace of the type used with a coal consumption of 2.75 per cent. of its dry weight. The calcine will contain about 0.6 per cent. sulphur. About 40 per cent. of the copper is water-soluble.

It requires about 20 per cent. of the weight of the calcine in weight of solution to saturate the charge. This assumes the solutions at a specific gravity of 1.00, while in reality they have a specific gravity of about 1.25.

It requires about 40 per cent. of the weight of the charge in wash water for a reasonably good wash.

The acid consumption will not exceed 50 lb. $H_2SO$ per ton of charge and the salt lost in solution discard will not be more than 1 per cent. of the weight of calcine, probably much less. By figuring acid consumptions on each leach, and using acid content of each solution, before going on and after coming off the calcine, the acid consumption on the first 14 leaches averages about 25 lb. per ton. On the last six, 50 lb. of acid per ton was added. This may have given somewhat better results, but not very much so. It seems as though perhaps the extra acid of the 50-lb. consumption was used in taking up iron and alumina, and had very little effect on the copper remaining in the charge.

The silver has a tendency to precipitate on the lead linings to a small extent. This would not offer much difficulty, as the lead rapidly becomes coated and precipitation ceases. The solutions, on cooling and on the addition of water, drop some of the silver out as silver chloride. This forms in the bottom of the solution tank to more or less extent and has to be cleaned up periodically. All of the silver in solution precipitated in the scrap-iron launders with no trouble whatever.

Under conditions which would apply in a large plant, it is expected that an 85 per cent. extraction can be made on the copper, and very probably 86 or 87 per cent. A tailing carrying between 2 and $2\frac{1}{4}$ lb. of copper per ton should be made. In a plant as small as the 80-ton plant, and built for temporary use, a great many petty annoyances are encountered, as the running of the furnace, and therefore of the whole plant, depended on so many small pieces of machinery in the conveying and cooling equipment. Not 10 per cent. of the furnace shutdowns were caused by troubles with the furnace itself. Naturally, the furnace does much better roasting, and with less coal consumption, when it is running continuously or nearly so.

No salt is necessary in the roast for the better extraction of the copper. It would increase the silver extraction from 75 to 90 per cent, but this extra 15 per cent of the silver recovered would not pay for increased cost of salt, installation, and operation of an apparatus to catch the values in the gases. This recovery of fume values would probably not be much over 90 per cent. The chloridizing of the silver is done in the leaching tanks.

### Precipitation of Copper from Solution at Anaconda

The paper on this subject by **Frederick Laist** and **F. F. Frick** points out that there are three general classes of precipitation methods: First, the use of iron, scrap

PHOTOGRAPH TAKEN AT THE UTAH MEETING OF THE AMERICAN INSTITUTE

or sponge; seconds, electrolytic deposition, and third, the use of some gas or reagent by which the copper is obtained, usually in the form of an intermediate precipitate which requires further treatment. For example, the precipitation of the copper as $Cu_2Cl_2$ from chloride solutions, with $SO_2$ gas.

The use of iron is adapted to almost any process. It has the great advantage of extreme simplicity, and the recovery of the copper and any values present in a highly concentrated, easily treatable form. The disadvantages are the cost in isolated places, the uncertainty of the scrap-iron market, and the fouling of the leaching solutions. The latter is a serious factor, when a reagent such as salt is used in them, which makes necessary their re-use.

Where applicable, electrolytic deposition is very attractive. The copper is obtained in a form directly marketable, there is a regeneration of acid and no fouling of solutions. Unfortunately, chloride solutions do not lend themselves to electrolysis. An entirely satisfactory anode material has not yet been discovered, although magnetic, apart from being rather brittle, seems to answer the requirements fairly well.

The use of a method of the third class is involved in many special leaching processes, and is highly attractive theoretically. Such methods usually involve regeneration of leaching solutions, no fouling of solutions, and the use of some cheap reagent, as lime, or a by-product of the process itself, or of some process such as smelting. Some method of this kind is undoubtedly that of the future where electrolytic deposition is not applicable.

The copper solution from the 80-ton leaching plant, in which the sand-treatment method now being installed on a large scale was developed, averaged Cu, 1.91; $Fe_2O_3 + Al_2O_3$, 3.88; NaCl, 8.3 per cent.; Ag. 0.634 oz. The copper content of this solution cannot be increased much economically. The application of this solution to successive lots of roasted tailing, from which about 10 lb. of copper per ton can be recovered, would necessitate excessive washing of the tailing. The copper can be precipitated from this solution by means of scrap iron, the cement copper going directly to the blast furnaces or converters. The use of sponge iron is more attractive than the use of scrap iron, however. It can be made from calcines which contain about 50 per cent. iron. This makes the process independent of the scrap-iron market. But the use of iron necessitates the discard of about one-fourth of the solution each time to stop the accumulation of iron sulphate, and this leads to the loss of much valuable salt.

Owing to its high chlorine content the solution is not adapted to electrolysis. With a view to getting something better than scrap iron, precipitation experiments have been and are being conducted on precipitation by sulphuretted hydrogen made from matte (also from calcium sulphate), sponge iron from calcined concentrates, and sulphur dioxide from roasting-furnace gases.

The authors describe first their experiments with hydrogen sulphide as precipitant, then with sponge iron, and finally precipitation with sulphur dioxide.

To reduce the cuprous chloride, the authors have developed three different methods. First, precipitation with sponge iron ($Cu_2Cl_2 + Fe = 2Cu + FeCl_2$). Second, reductions with coke with limestone present to flux and hold the chlorine. Third, electrolytic reduction. The results obtained with these three methods are described in the paper.

The final conclusion of the authors is as follows:

At present it seems advisable to precipitate the copper directly from the copper solutions of the 2000-ton sands-leaching plant with sponge iron. The precipitation of the copper from such solutions with sponge iron is being worked out and promises to be simple. Until the leaching process is established on a definite operating basis it does not seem advisable to introduce a complicated precipitation method.

The acid plant now building will have ample capacity for the first 2000-ton leaching unit. When the time comes to build further units, the installation of an $SO_2$ precipitation plant will depend on considerations of first cost of acid and precipitation plants, cost of operation and other factors which undoubtedly will develop.

### Leaching Copper Products at the Steptoe Works

The paper by W. L. Austin describes a small copper-leaching annex to the Steptoe metallurgical plant, where ore of the Nevada Consolidated Copper Co. is beneficiated. This copper-leaching annex has been treating flue dust from roasting-furnace dust chambers, together with a siliceous oxidized ore. This leaching plant was designed to obviate smelting low-grade siliceous flue dust, which interfered with the operation of the reverberatories by forming a blanket on the charge.

The major portion of the copper content of the

OF MINING ENGINEERS WITH MINE OF UTAH COPPER COMPANY AS BACKGROUND

flue dust accumulating in the upper chambers of the roaster flue, and at the stack, is water soluble, and also contains much free sulphuric acid and soluble sulphates. It was found that sufficient acid could be obtained by mixing this material with water to provide a lixiviant for leaching the siliceous copper ore mentioned. This was the sole source of the lixiviant.

The flue dust analyzed copper 3 per cent, $SiO_2$ 23, Fe 4., CaO + MgO 3., $Al_2O_3$ 6., free $H_2SO_4$ 20., $SO_3$ combined as sulphate 25., $H_2O$ combined with the sulphates 11, O 2.5. Copper soluble in dilute $H_2SO_4$ 2.56.

The oxidized ore, locally known as "carbonate," contains 3.5 per cent Cu, 71 $SiO_2$, 2 Fe, 9.5 $Al_2O$ — Copper soluble in dilute $H_2SO$ 3.23. The copper in this ore is largely mineralized as silicate.

The method of operation pursued at the Steptoe plant consists in hydraulicking the piles of flue dust which have been withdrawn from the dust chambers, as an economical means of dissolving the soluble contents and of transportation to the tanks. The stream of water is conducted to vats, or impounded in dams, where the mud is allowed to settle. The clear solution resulting, which contains the soluble salts and is now the lixiviant, is drawn from these reservoirs to a wooden vat, fitted with a filter bottom. This is the ore-leaching vat proper. It is 40 ft. in diameter and 10 ft. deep. It is filled with crushed "carbonate" ore to a depth of 7 ft.; the ore column through which percolation of ¼-in. material is effected is therefore about 7 ft. high.

The excess space in this vat is used to store the lixiviant, for the hydraulicking operation is intermittent, while ore leaching is continuous. Enough lixiviant is accumulated above the charge in this vat to continue leaching during the night.

If the filtrate from the ore leaching vat (the lixivium) still contains considerable free acid, it is pumped back and passed through the ore bed a second time. Otherwise it is allowed to flow through a filter of "carbonate" ore, and thence over scrap iron placed in precipitating boxes.

About 85 per cent of the free acid carried by the lixiviant is utilized in the ore-leaching vat, the remaining 15 per cent. being left in the lixivium flowing over the scrap iron, to prevent formation of basic iron salts and insuring clean precipitate. About 2 lb. of scrap iron are consumed per pound of precipitate produced.

The cost of the copper recovered from the flue dust and siliceous "carbonate" ore capacity is approximately 8 cents per pound.

### Leaching Experiments on the Ajo Ores

The paper by **Stuart Croasdale** gives a full account of the experiments carried out by him on the treatment of ores from the New Cornelia copper mine, Ajo mountains, Arizona, for the Calumet & Arizona Copper Company. Incidental with this problem was the utilization of a large amount of low-grade pyrite in the Bisbee mines of the company, provided this could be accomplished by any feasible method.

The ore deposit is unusual. It consists of an intrusive plug of monzonite or granite porphyry. Chalcopyrite, bornite, and magnetite are finely disseminated throughout the magma in sufficient quantities to make the greater part of the mass commercial ore to a certain depth.

The conditions of the problem demanded simplicity of process and large scale of operations. Two methods of *leaching* treatment were available, and both are entirely reliable and feasible under the conditions involved. One of these is the old Henderson process of roasting with salt, and the other is leaching the raw ore with sulphuric acid. Under the head of "chloridizing roast with salt," the author includes the so-called sulphatizing roast of Mr. Wedge, in which he finds the addition of a small percentage of salt very beneficial; and also the modification used by Mr. Laist at Anaconda, in which he reduces the consumption of salt, as well as the losses by volatilization, by giving the ore a preliminary roast before adding the salt.

A comparison of these two methods may be made briefly as follows:

By using the chloridizing roast, all ores on the property could be treated by the same process—oxidized, sulphide, and intermediate. This would mean the construction of only one plant. The average extraction of the copper would probably be higher than that obtained from acid leaching and the small amount of silver in the ore would be recovered to a large extent. By mixing the ores, little if any sulphur would have to be added as pyrite. The only chemicals required would be salt, to the extent of 5 to 10 per cent. of the ore treated, and possibly a small amount of pyrite ore. Both of these could be transported in ordinary freight cars. There would be less corrosive solutions to handle. There would be a minimum amount of iron and alumina passing into solution. There would be no appreciable absorption of copper by slimes.

On the other hand, this method would require dry crushing of the ore to 20 or 40 mesh, which would be troublesome if not prohibitive on the oxidized ores on account of the difficulty in controlling the poisonous dust, in addition to the expense of grinding. It would involve a roasting cost. It would mean a more expensive plant, for the same capacity of operation, mainly on account of the slower percolation of the fine material, which would require a much larger vat area of less depth to hold the tonnage required. It would mean a supply of cheap salt. A chemical precipitant would probably have to be used to recover the copper.

By leaching with sulphuric acid, the oxidized ore can be treated raw and need not be crushed finer than ½ in. or 2-mesh size, or perhaps coarser, as the experiments of the author have shown. Owing to the high oxidation of the surface ores and apparently small zone of partly oxidized ores, a large tonnage can be expected to give a comparatively high extraction by this method. Sulphuric acid can be made as a by-product at the roasting plant of the Calumet & Arizona Company at Douglas, or if the calcines are converted into sponge iron and used as a precipitant for copper, the low-grade pyrite from Bisbee can be cheaply transported and acid made at the mine. If electrolytic precipitation can be used, a small percentage of the acid consumed can be regenerated. This method of extraction will permit of less expensive plant construction for the oxidized ores.

On the other hand, sulphuric acid alone will extract none of the copper existing as sulphide, only half of the copper existing as cuprite, and may be indifferent about the silicate of copper. It will extract none of the precious metals. Owing to the character of the oxidation of the ore, considerable iron and alumina pass into solution as readily as the copper, which will seriously interfere with any form of electrolytic precipitation and render the amount of acid regenerated a doubtful asset when compared with the amount consumed. As an offset to this objection, some of the iron is in a ferric condition, which assists materially in the solution of the minerals mentioned above.

If acid is made at Douglas, it will have to be transported several hundred miles in tank cars, which will have to be returned empty. If acid is made at the mine from low-grade pyrite, a gain will be made in transportation, but the cost of an acid plant will be added to the cost of the leaching plant and the calcines will have to be utilized. Almost an entirely new plant will have to be constructed for treatment of the intermediate and sulphide ores.

The problem is clearly one in arithmetic as well as metallurgy.

Laboratory experiments were made with both methods, experimental plant tests only with the acid leaching process. These tests are described in great detail in the paper.

The second part of the paper deals with *precipitation* of the copper from solution. The following precipitants are discussed: Natural sulphides of iron (unsuccessful, as far as the experiments went); artificial sulphides of iron (a failure); sponge iron (it seems feasible to metallize calcines for copper precipitation at a cost of not over $5 per ton of metallic iron); pig iron (the consumption of iron need not exceed 1 lb. for each pound of copper precipitated, provided the solutions are neutralized before precipitation) and finally electrolytic precipitation.

The vital factors governing electrolytic precipitation are cost of power, material for anodes, and interference of other metals.

The power required for deposition from clean copper sulphate solutions is about eight or ten times that required for refining purposes, or about 1 kw. per pound of copper deposited. The most economical current density is between 10 and 11 amperes per square foot and the voltage required is about 2 volts, although with magnetite anodes it is said a current density of 15 amperes can be used. With an average cost of electric power of not more than 1c. per kw. the power costs for this method of precipitation need not be prohibitive.

The anode material heretofore has been confined to lead or antimonial lead. Fused magnetite is now being tried and is said to be very satisfactory, although fragile and expensive. Its merits are yet to be demonstrated on a large scale. Lead anodes are gradually consumed, forming the peroxide of lead, which can be collected, reduced and used over again if necessary.

Interference of other metals has proved the chief stumbling block in most of the attempts to use the electrolytic method for the recovery of copper. Arsenic and antimony are troublesome, but are seldom found in appreciable quantities in leachable ores. Iron is the principal source of trouble and with it may be considered manganese if present, for its influence is substantially the same as iron. Iron, by its alternate oxidation and reduction, consumes electrical energy without the deposition of copper. It must, therefore, be rendered innocuous by one of the following methods: Removal by precipitation, the use of diaphragms, or the use of depolarizers.

The first two methods seem impractical, but the use of a depolarizer seems to offer a way out of this difficulty. The most feasible depolarizer and perhaps the only one sufficiently cheap for this purpose is sulphur dioxide. This has some advantages and some serious disadvantages. Theoretically, sulphur dioxide used in this manner will regenerate 3 lb. of acid for each pound of copper deposited. In experimental practice, 2 lb. has been the maximum obtained, owing to difficulties of manipulation. A certain amount of electromotive force is also generated in the direction of the current used, which reduces power consumption. These advantages, however, are more apparent than real.

If much iron and alumina pass into solution from the ore, the actual acid regenerated in the electrolytic cells is relatively too small to be of any importance. On these Ajo ores, granting the best possible regeneration of acid from electrolytic cells, the author estimated that 75 per cent. of the acid used will have to be made in an acid plant. In actual practice it would no doubt exceed this amount.

The mechanical difficulties in making the copper lixiviums absorb sufficient sulphur dioxide gas to produce the desired results have not been solved. Introduction of the gas into the electrolytic cells at the anode secures a very small absorption and renders the electrolytic plant uninhabitable for human beings. Acid makers of experience do not offer much hope of success for absorption of this gas by means of scrubbing towers.

Those who have tried to make sulphur dioxide act as a depolarizer on a commercial scale report these claims a fallacy.

Moreover, it has been found that when electrolytes containing sulphur dioxide are used the current density must be reduced to the neighborhood of 3 amperes per square foot in order to get a satisfactory deposition of the copper. This means an electrolytic plant installation three times the size ordinarily required.

It has been found impracticable to deposit copper from electrolytes containing less than 1 per cent. copper. The average lixivium including enough wash water and acid to maintain a standard electrolyte will average between 1.5 and 2 per cent. copper. Assuming then, for the sake of argument, that 35 to 50 per cent. of the copper can be deposited in good form by electrolysis (35 per cent. is actually the case in the only plant in operation), if relatively large quantities of iron and alumina pass into solution at each cycle of the lixiviant it will be necessary to discard the entire lixiviant in a short time or a portion of it at each cycle, in which the copper will have to precipitated by a chemical reagent. This discarded lixivium will either be strongly acid, or, if neutralized by fresh ore, will carry its full quota of copper. In any leaching operation, there will be also a gradual accumulation of wash water or weak solutions, which will have to be treated with a chemical precipitant.

The conditions governing the successful deposition of copper from solution by electrolysis have been determined quite conclusively after long and careful experimentation by men skilled in the art.

With ores that will yield lixiviums free from interfering elements this method will no doubt prove a commercial success in spite of its expensive installation, but with ores like these where the iron passes into solution as readily as the copper, when the raw ore is leached with acid, it is almost a mathematical certainty that electrolytic precipitation cannot be made a commercial success and further experimentation along this line is useless.

A much more feasible method of overcoming this difficulty with iron would be to keep it from going into solution in the first place. This might be done by roasting the ore after crushing to the size required for leaching. The expense would be small. While there might be some danger of forming insoluble ferrites of copper, the iron and alumina would be rendered relatively insoluble in acid, the ore would be made more porous for leaching, there would be no argillaceous slimes to absorb valuable constituents, the copper sulphides and cuprite would be rendered soluble and the lixiviums might be clean enough for electrolysis.

The author's work was finished before this was tried.

### Slime-Concentrating Plant at Anaconda

The paper by **Frederick Laist** and **Albert F. Wiggin** describes the new slime-concentrating plant at the Washoe Reduction Works, Anaconda, put into operation during March, 1914. This plant, which has a capacity of 26,000,000 gallons of slime pulp carrying 2,500 tons of solid matter per day, consists of Dorr thickeners and Anaconda multiple-deck slime concentrators. This plant is the culmination of a great deal of experimental work extending over a considerable period of time. This work is described in the paper.

The authors discuss the sources and amount of slime and its composition and then describe the experimental development work at Great Falls and Anaconda. These experiments related to slime thickening devices, slime-concentrators, dewatering of the slime-plant concentrate, the use of chemicals to accelerate the settlement of slime, and the effect of temperature upon the settlement of slime.

Finally a description of the Anaconda slime plant is given. The plant consists of three divisions, the slime-thickening division, the concentrating division, and the concentrate-dewatering division.

### Chloridizing Leaching at Park City

The paper by **Theodore P. Holt** describes the plant of the Mines Operating Company at Park City, Utah, which was designed to treat the low-grade fillings in the old stopes of the Ontario mines. These fillings carry 6 to 14 oz. of silver, 1 to 2 lb. copper, 0.01 to 0.015 oz. of gold, and a small percentage of lead and zinc. The treatment consists in mixing the crushed ore with coal dust and salt and then roasting in a new type of furnace by combustion of the contained fuel. The roasted ore is leached with an acid salt solution to dissolve the silver, gold, copper, and lead. At present these metals are precipitated together on scrap iron and the product sold to a refinery.

The only new feature of importance in this scheme of treatment is the roasting process, which makes possible the chloridizing of ores without any loss of the valuable metals, and at a very low cost.

A paper by **James C. Ray** on microscopic study of Butte ores was finally presented and illustrated with stereopticon views.

### Tuesday

On Tuesday the members were taken by a special train to the Bingham mines of the Utah Copper Company. The Bureau of Mines' rescue car was attached to the train for inspection. A rescue demonstration followed the visit to the Magna mill.

The Garfield smelter was next visited, where the reverberatory furnaces fired by oil and coal dust, and the nearly finished Cottrell electrostatic precipitation plant for converter fumes were of special interest.

In the evening session William Wraith presided, and the following papers were presented in the smelting symposium:

W. H. Howard, "Electric Fume Precipitation at Garfield."

L. D. Anderson, "Effects of the Bag House on the Metallurgy of Lead."

Lawrence Addicks, "Nodulizing Blast-Furnace Flue Dust."

E. L. Newhouse, "Lead Smelting at East Helena, Montana."

W. W. Norton, "A Comparison of the Huntington-Heberlein and Dwight-Lloyd Processes."

G. P. Hulst, "The International Lead Refining Plant."

On account of limitations of space, abstracts of these papers must be reserved for our next issue.

A complimentary smoker at the University Club followed the session.

### Wednesday

On Wednesday the party was taken by a special train to the smelters at Murray, Midvale, and Tooele, Utah.

At the technical session in the evening C. W. Whitley presided. The subject was a symposium on zinc. The following papers were presented:

Dorsey A. Lyon and S. S. Arentz, "Losses of Zinc in Mining, Milling and Smelting."

R. D. Divine, "Separation of Lead, Zinc and Antimony Oxides.

S. E. Bretherton, "Treatment of Complex Ores."

H. A. Wentworth, "Electrostatic Separation at Midvale."

Earl T. Bardwell, "Effect of Annealing Upon Refined Copper."

C. D. Demond, "Economy and Efficiency in Reverberatory Smelting."

E. Horton Jones, "Unit Construction Costs for the New Arizona Copper Company Smelting Plant."

Dorsey A. Lyon and Robert M. Keeney, "Melting of Cathode Copper in the Electric Furnace."

C. R. Kuzell and I. H. Wigton, "Curves for the Sensible Heat Capacity of Furnace Gases."

L. O. Howard, "Basic Lines Converter Practice at the Old Dominion Plant."

On account of limitation of space abstracts of these papers must be reserved for later issues.

### Thursday

At the Thursday morning session Sidney J. Jennings presided, and the following papers were presented:

John Van N. Dorr, "The Dorr Hydrometallurgical Apparatus."

G. H. Clevenger, "The Mill and Metallurgical Practice of the Nipissing Mining Company.

Robert H. Bedford and William Hague, "Tests of Rock Drills at North Star Mine, California."

E. D. Gardner, "Mining Claims Within the National Forest."

A large party made an excursion to Park City, where the Mines Operating Company's plant was visited, in which low silver ores are chloridized as described in the paper of T. P. Holt, noted above.

### Banquet

On Friday night a banquet was held in the grill room, instead of the roof garden, of the Hotel Utah. It was a brilliant social event, graced by the presence of many ladies. Dancing followed.

The total attendance was about three hundred. W. L. Saunders acted as toastmaster, and speeches were made by President B. B. Thayer on "The American Institute of Mining Engineers," Bradley Stoughton on "Institute Ideals," Governor William Spry on "Utah," and E. M. Allison on "The General State of Affairs."

The whole meeting was most successful. Salt Lake City is wonderfully situated for such a convention on account of the great variety of mining and metallurgical operations, many of them being conducted on a tremendous scale. The hospitality of the Utah members was overwhelming.

## Synopsis of Recent Chemical and Metallurgical Literature

### Iron and Steel

**Finishing Temperatures and Properties of Rails.**—The main objects of an investigation recently completed by the Bureau of Standards, Department of Commerce, into the finishing temperatures and properties of rails were to determine, from measurements taken in representative rail mills, the present American practice regarding the temperatures at which rails are rolled; to demonstrate the ease and accuracy with which such temperatures may be measured; to find out what the "shrinkage clause" in rail specifications really means; and finally to determine for rail steels some of the physical properties, particularly those of interest in manufacture. Observations were taken with an optical pyrometer of ingot and finishing temperatures of rails in four representative mills. There is practical uniformity among the several mills for the rolling temperatures of ingots for steel rails, the range being from 1080° C. (1975° F.) to 1140° C. (2085° F.). There is no very considerable difference among the finishing temperatures of the rails as observed at the hot saws for the several mills, the range being about 880° C. (1615° F.) to 990° C. (1815° F.). Or, in other words, the four mills all finished their rails to within 50° C. of 935° C. (1715° F.) on the average. This temperature of 935° C. is 270° C. (520° F.) above the mean value, 665° C. (1230° F.) of the critical ranges of these rail steels. Concerning the distribution of temperatures within the head of a cooling rail, it is shown that the center of the head is some 50° C. (120° F.) to 60° C. hotter than the optical pyrometer reading at 935° C., therefore the center of the head is finished on the average at about 325° C. (615° F.) above the critical range for 100-lb. sections.

Chemical analyses and microphotographic examinations were also made and the mechanical properties determined for a number of samples of rail, the rolling of which had been observed. From a comparison of these few observations, there appears to be not a sufficient degree of correlation to warrant associating very specifically any of the characteristics defined by these three methods of examination, either with the temperatures of rolling here observed or with each other. The following thermal properties of these rail steels were determined in the laboratory:

The critical range on heating is located (maximum) to within 7° C. of 732° C. (1350° F.) for the 10 samples of open-hearth and Bessemer steels examined. On cooling the critical range lies between the limits 680° C. (1256° F.) and 650° (1202° F.).

The melting or freezing range for rail steel extends from about 1470° C. (2680° F.) to nearly the melting point of iron, located at 1530° C. (2786° F.).

The expansion for open-hearth and Bessemer steels is not the same. Above 800° C. (1470° F.) the expansion for both increases linearly with temperature and the linear coefficient per degree centigrade has the following mean values between 0° and 1000° C.

(1) For Bessemer steel (carbon .40 to .50%): alpha = 0.0000146.

(2) For open-hearth steel (carbon .65 to .70%): alpha = 0.0000156 to 0.0000161.

The average composition of the Bessemers was carbon = 0.40 to 0.50 and manganese = 0.76 to 0.93; of the open hearths, carbon = 0.66 to 0.70 and manganese = 0.66 to 0.72.

The American Society for Testing Materials in 1909 limited the shrinkage allowance on 100-pound sections to 6¾ inches in 33 feet, or to an equivalent of 1947° F. (1064° C.) for O. H. and 2055° F. (1134° C.) for Bessemer rails. This specification is still in force. Such a shrinkage clause therefore does not serve the avowed purpose of limiting the finishing temperatures to a value slightly above the critical range.

In conclusion, it should be emphasized that the various series of observations recorded in this investigation are of but a preliminary nature and do not pretend to solve the question of the relations between temperature of rolling and the properties of rails. It would seem desirable to make a much more complete and comprehensive study of the various matters mentioned and of related questions than has hitherto been attempted, and on a scale commensurate with the importance to the community of the problem of sound rails.

### Alloys

**Bronze.**—In his recent paper before the (British) Institute of Metals, Mr. **John Dewrance** draws attention to the desirability of modifying the composition of bronze with the object of preserving its strength when used for high pressure and superheated steam. The paper gives the results of a large number of experiments which go to establish the fact that the addition of a half of one per cent of lead preserves the strength of the bronze up to 500 deg. and that without the lead bronze loses its strength at 350 deg. F. It is suggested that as lead has this effect it is probable that further investigation might prove that some other ingredient might preserve the strength of bronze at even a higher temperature. It is also shown that oxygen in bronze does not reduce the strength within practical limits.

**Vanadium in Brass.**—In a recent paper before the (British) Institute of Metals on the effect of vanadium on the constitution of brass containing 50 to 60 per cent copper, Messrs. **R. J. Dunn** and **O. F. Hudson**

describe experiments which were carried out with the object of ascertaining what, if any, was the effect of small quantities of vanadium on the constitution and structure of certain copper-zinc alloys, particularly with reference to the change which occurs at about 460 deg. C. in those brasses which contain the beta phase. A number of alloys containing small percentages of vanadium and inconsiderable quantities of impurities resulting from the reduction of pure vanadic acid by means of aluminium were tested thermally and microscopically. It was found that the critical point at 460 deg. C. was only slightly affected by vanadium, 1 per cent raising it not more than 10 deg. C. It was also found that the usual structure of brasses containing 50-60 per cent of copper is not greatly modified by the presence of small quantities of vanadium. Thus the observation of Carpenter that 1 per cent of vanadium causes the complete structural resolution of beta into alpha and gamma was not confirmed. Some of the alloys were subjected to prolonged annealing at temperatures just below 460 deg. C., and the conclusion arrived at was the vanadium to the extent of at least 1 per cent appears to have no influence on the structural stability of the beta constituent of the copper-zinc alloys. The authors also consider that if any structural resolution of beta into alpha and gamma follows the addition of cupro-vanadium to brass the result probably is due rather to the relatively large amounts of aluminium usually present in commercial samples than to the small percentage of vanadium remaining in the finished brass. In an appendix a brief description is given of the method of analysis adopted.

**Corrosion of Brasses.**—In a recent paper before the (British) Institute of Metals on the microchemistry of corrosion **Mr. Samuel Whyte** and **Dr. Cecil H. Desch** discuss the effect of electrolytic corrosion on the a-brasses of copper and zinc. The total corrosion is less than in the b-brasses, and there is less preferential removal of zinc. The alloy containing 1 per cent of tin is at first more corroded than a 70:30 brass, but as time goes on the corrosion is lessened, owing to the formation of a very tough layer of basic salts. The protective action of tin is attributed to this cause. One per cent of lead does not retard corrosion, as the residual coppery layer is very open in texture, but an alloy with 2 per cent of lead, (70:28:2) becomes covered with a very firmly adherent layer. This alloy was much less corroded than any of the others examined. Brass condenser tubes, corroded during service, have a structure which may be exactly reproduced by the application of an external electromotive force. This point is proved by photomicrographs. The apparent differences depend on the rate of corrosion and the supply of oxygen. When corrosion is slow and the oxygen supply abundant, the spongy layer of copper is converted into oxide as fast as it is formed, but otherwise a metallic dezincified layer remains.

**Nickel in Copper-Aluminium Alloys.**—In their recent paper before the (British) Institute of Metals **Professor A. A. Read** and **Mr. R. H. Greaves** discuss the influence of varying percentages of nickel on some mechanical and physical properties of the copper-aluminium alloys with 5 and 10 per cent of aluminium respectively. Hot rolling and forging tests showed that apart from increased hardness, and the necessity of a higher rolling temperature, the behavior on hot rolling of alloys with up to $7\frac{1}{2}$ per cent of nicked was identical with that of the pure copper-aluminium alloys. Malleability and ductility are rapidly reduced by nickel in the 10 per cent aluminium series, but with 5 per cent of aluminium the presence of nickel increased the ductility as judged by the wire drawing tests. The main features of the tensile, hardness and alternating stress tests considered in conjunction with the microstructure may be stated briefly as follows:

(1) Alloys with 10 Per Cent of Aluminium.—Nickel up to 10 per cent in the chill castings gives increased maximum stress and yield point at the expense of elongation and reduction of area: 5 per cent of nickel gives maximum hardness; 5 per cent of nickel improves the annealed metal and diminishes the detrimental effect of annealing on the 10 per cent aluminium alloy. This composition corresponds to the limit of the alpha plus beta structure, increase of nickel above 5 per cent being accompanied by the separation of a blue constituent in place of beta. The effect of quenching on these alloys is similar to that on the 10 per cent aluminium bronze, but becomes less marked as the nickel increases.

(2) Alloys with 5 Per Cent of Aluminium.—Both in the chill castings and annealed rods, nickel has little effect on the hardness, maximum stress and yield point until 5 per cent is present. The ductility, however, is greatly increased by 1 per cent of nickel. With less than 5 per cent of nickel, the alloys consist of a homogeneous solid solution; with more than 5 per cent a second constituent separates on slow cooling, causing in the annealed rods a rapid increase in hardness, maximum stress and yield point with an accompanying diminution in elongation and reduction of area. The effect of quenching on the alloys with 5 per cent of nickel and over is to retain the second constituent in solid solution and thus to increase the ductility, while the hardness, maximum stress and yield point diminish. The rate of cooling need not be very great, for air-cooled rods gave results which approximate to those of the quenched.

The presence of nickel makes practically no difference to the specific gravity of these alloys: their melting points are raised, and conductivity for electricity greatly diminished. Corrosion by sea water is greatly reduced by the presence of nickel: there is no difference in behavior between the annealed and cold rolled metal. All the alloys with 5 and 10 per cent of aluminium and varying nickel behaved better both in fresh and sea water than either Muntz metal or naval brass.

**Rapid Cooling of Binary Alloys.**—Before the recent meeting of the (British) Institute of Metals **Mr. G. H. Gulliver** presented a paper which was a continuation of one read before the Institute last March. The methods then explained were now extended, so that the proportions of the constituents of a rapidly cooled binary alloy could be determined with a close degree of approximation whatever the curvature of liquidus and solidus. Results were given for the more important alloys of the copper-tin and the copper-zinc series, and for the copper-nickel series. A formula was devised for calculating the proportions of the constituents obtained with moderate rates of cooling when the liquidus and solidus are sensibly straight, and the results obtained from this for the lead-tin series were given.

**Solidification of Metals from the Liquid State.**—At the recent meeting of the (British) Institute of Metals **Dr. Cecil H. Desch** presented his first report on this subject to the Beilby Price Committee. The arrangement of crystal grains in a metal or alloy has usually been accounted for by growth of crystallites from independent centers. Against this, Quincke has proposed the hypothesis of foam-cells. On this view, the liquid separates immediately before crystallizing, into two liquids, which arrange themselves to form a foam, and crystallization then takes place within the foam-cells. Quincke has applied the hypothesis to the explanation of many of the properties of metals. Several recent writers have also sought to connect the cellular structure with the prismatic partitioning of cooling liquids by convection currents. Whilst this arrangement may possibly be traced in some metals when cast in thin sheets, it cannot account for the structure of ingots or other large masses. The passage of metals in certain cases through an intermediate liquid-crystalline state has also been assumed, but not yet established. A review of the existing evidence suggests that several distinct cellular structures have often been confounded, and that a common origin has been assumed for structures which have a merely geometrical similarity.

The effect of undercooling, and the possibility of existence of two distinct classes of undercooled liquids is also discussed, as well as the changes of volume which occur during fusion and solidification. The determination of such changes is shown to be complicated by other factors, so that an increase in the external dimensions of a casting does not invariably represent an actual increase in the volume of metal. Lastly, the programme of experimental work now in progress, with the object of testing and comparing the hypotheses mentioned above, is briefly outlined.

**Muntz Metal.**—At the recent meeting of the (British) Institute of Metals Dr. J. E. Stead and Mr. H. G. A. Stedman presented a paper on the correlation of composition heat, heat treatment, structure and mechanical properties of Muntz metal. The authors having obtained a set of ½-in. bars of pure Muntz metal for the purpose of the research, heated them in duplicate in a tube furnace electrically heated for 48 hours to various temperatures ranging between about 500 deg. C. and 860 deg. C., after which treatment one of the heated bars, in each set, was quenched in cold water, the companion bar being allowed to cool in air. The cold bars were then examined microscopically and tested mechanically. Other bars were heated for three months at about 430 deg. C., and at 270 deg. C. for 984 hours and they were also tested and examined. The results appeared to dispose of the idea, held in some quarters, that Muntz metal could be burnt by high heating, and that quenching tended to soften brass, for while the annealed metal cooled in air had a tenacity of about 25 tons, the same material quenched from 812 deg. C. had a tenacity of 29½ tons—an increase of about 4½ tons.

The practical importance of the research is undoubted, as it shows:

First—That Muntz metal should not be annealed at temperatures between 750 deg. C. and 800 deg. C., as this is a range of danger, but it may be heated above 800 deg. C. without destroying its good quality.

Second—That it is made homogeneous and can be hardened to a considerable degree by heating to and quenching from above 800 deg. C.

Third—That the maximum degree of softness is obtained by long heating at the temperature of melting zinc—about 430 deg. C.

Fourth—That Muntz metal is very slightly oxidized by annealing even at 800 deg. C., and that the scale produced on the surface consists of zinc oxide free from copper.

The final part of the paper is devoted to the description of methods of tinting brasses so as to reveal their structure, and to the effect of hard drawing in leading to fractures in Muntz metal during service.

**Report of Committee on Nomenclature of Alloys.**—At the recent annual meeting of the (British) Institute of Metals in London the committee, consisting of representatives of the Institute of Metals, the Institution of Mechanical Engineers, the Institution of Electrical Engineers, the Institution of Naval Architects, the Institution of Engineers and Shipbuilders in Scotland, the North-East Coast Institution of Engineers and Shipbuilders and the Society of Chemical Industry, (chairman, Dr. W. Rosenhain, F.R.S.), present a unanimous report in which they recommend the adoption, first of a systematic nomenclature in which alloys are denoted by the names of their constituent metals in English, arranged in increasing order of percentage present in the alloys. This systematic nomenclature is intended chiefly for scientific and other purposes where its precise character more than outweighs its cumbrousness. The committee next recommends that a system of "practical" nomenclature should be set up consisting of "practical" names which are to serve as every-day abbreviations of the systematic or scientific names. The definition of current practical names on this basis has so far only been attempted in regard to the two important terms, "brass" and "bronze." The definition of "brass" adopted by the committee is that it is to be used as an abbreviation of the words "zinc-copper" as employed in the systematic nomenclature; when employed alone it indicates that the alloys are pure zinc-copper. Where the presence of other metals is to be indicated their names are to be prefixed to the term, forming such words as tin-brass, aluminium-brass, manganese-brass, etc. Similarly the term "bronze" is defined as an abbreviation for "tin-copper" as used in the systematic nomenclature, the definitions in other respects being identical as that for "brass." The committee is not yet prepared to recommend definitions of further practical terms, but the two terms defined represent the most widely used alloys, and their general adoption as thus defined would do much to remedy the state of confusion which exists at the present time. The committee, therefore, appeal to all those interested in the progress of the industries and sciences connected with metals to use their best endeavors to support and carry out the recommendations of the committee.

## Oils

**Iodine Number of Linseed and Petroleum Oils.**—The determination of the iodine number of linseed and petroleum oils according to the Hanus method has just been completed by the Bureau of Standards of the Department of Commerce and the results published in Technologic Paper Number 37. Each of the three factors, weight of sample, time of absorption, and amount of Hanus solution was studied for a series of burnt linseed oils and petroleum oils. The results produced by variation of one of the factors, the others remaining constant, are reproduced graphically. Variations of weight of the raw linseed oil show that a constant volume is obtained for weights of the oil up to 0.25 gram. Beyond this value, the iodine number decreases with increasing weight. For burnt linseed oils, the range of weight over which the iodine value is constant, decreases with increased burning of the oil. Petroleum oils, on the contrary, approach a constant value when 0.6 gram or more of the sample is taken. Varying the time of absorption from five to sixty minutes shows that the reaction approaches a maximum in about ten minutes. Thereafter, absorption is slow, and a few minutes one way or another has little effect on the value obtained. When the amount of Hanus solution is varied from 20 to 75 cc. the results indicate that the oil with the highest iodine number does not require the greatest excess of iodine to reach maximum absorption value. The effect of temperature on the value obtained is more marked for burnt linseed oils than for boiled or raw oils. The results as a whole indicate that concordance is obtained only when a prescribed procedure is followed with exactness. To obtain comparable results, a standard procedure should be followed in which the limits are strictly defined. This is particularly true of burnt linseed oils.

---

## Notes on Chemistry and Metallurgy in Great Britain

*(By our Special Correspondent)*

### Electric Mains Explosions

Last December the Board of Trade appointed a departmental committee to investigate the causes of explosions which were connected with cables laid in bitumen or sheathed with vulcanized bitumen at Hebburn, Nottingham and various other places. The report of this committee has recently been issued; and it appears that no serious cases of explosions have been disclosed nor was there any proof of instances where the supply was furnished by alternating current, by concentric mains, or by lead-covered paper-insulated cables, including three-core cables.

The faults occurred with single-core separate cables, sheathed with india rubber, or with vulcanized bitumen. And in all the cases of serious explosions which occurred in houses the cables were insulated with vulcanized bitumen; and such cables had either been drawn into bitumen casing or laid in bitumen on the solid system in troughs. Three causes of the deterioration of vulcanized bitumen are pointed out by the committee: (1) softening of the sheathing caused by coal gas; (2) corrosion of a conductor, consequent on a fault in a positive; and (3) faults to earth in a negative.

In the third class the conductor is not attached, but the insulating material is decomposed. Infiltration of moisture and osmosis render the bitumen pulpy and ultimately leakage occurs between positive and negative, or between middle and negative on the three-wire system, with the result that a short circuit is set up. When the resistance of the cable is sufficiently high the heat may only suffice to melt the adjacent bitumen which flows in, quenches the arc and seals the fault; but should the arc be persistent both the vulcanized bitumen sheathing and the trough bitumen would be melted and ultimately decomposed into gases which would form explosive mixtures with air.

However, the proportion of accidents which have occurred with vulcanized bitumen cables laid in solid bitumen has been so small in relation to the very large number of such cables in use that the committee is not prepared to recommend that approval of such system be discontinued. But the committee has arrived at the conclusion that the view that serious explosions are not likely to occur when pitch compound is used instead of bitumen for filling the troughs is justifiable. The committee is not able to recommend the exclusion of wood troughing in favor of iron or stoneware troughing, but does recommend the use of wooden troughing should be restricted to suitable soils.

In cases where separate mains are laid in troughing every cable should be laid in a separate trough; and there should be a space of not less than 2 in., tightly packed with earth or sand, between each trough. Separate mains for the supply of continuous current on the solid system should not be laid below pavement or close to the walls of houses; the bends at corners should be easy and the bitumen or pitch compound should be poured after the straight lengths have cooled.

With regard to the existing mains it is recommended that in all suspected cases of sharp corners the mains should be taken up and the corners eased, and that the service cables should be led into the houses in such a way as to preclude the possibility of the entrance of gas. Finally the committee recommend that the attention of engineers should be directed to the clauses of the Electric Lighting Act, 1899, and the Board of Trade regulations which enjoin notification of accidents by explosions or fire.

### The Effect of Temperature on the Properties of Gun Metal

At the recent Conference of Shipbuilders and Engineers at Newcastle Prof. J. G. Longbottom and Prof. A. Campion contributed a paper on the influence of varying temperature on Admiralty gunmetal. The metal used for the whole of the experiments was composed of 87.96 per cent of copper, 9.77 per cent of tin, 1.94 per cent of zinc, 0.18 per cent of lead, and 0.13 per cent of iron.

Two sets of tests were made. In the first cast bars 15 in. long were cut into lengths of 7.5 in., screwed with 7/8 Whitworth thread on the ends and turned down in the middle for a length of 3.5 in. to a diameter of 0.564 in.; while for the second set cast bars about 10 in. long were screwed with 1 1/8-in. thread for 2 in. at each end and turned down to a diameter of 0.798 in. for a length of about 5.5 in. in the middle.

During the tests the gunmetal bars with about 6 in. of each of the tension rods were placed in the center of an electric resistance furnace the temperature of which was taken with three platinum-iridium thermocouples. The results of the first series of tests showed very little change of strength from the initial temperature up to about 200 deg. C.; and, while the results from 200 deg. to 250 deg. were rather irregular, there was general indication of decrease of strength. As the temperature was further raised the strength continued to fall, until at 750 deg. there was practically none. At first there was an appearance of a slight increase of elongation with the increase of temperature, touching the maximum at 140 deg. C. As the temperature rose, however, it quickly fell, and at 350 deg. C. was less than 1.5 per cent. Thence up to 500 deg. there was but little alteration, with a slight tendency to an increase at about 400 deg. The modulus of elasticity was practically unaffected up to 200 deg., but diminished continuously with a further rise of temperature.

The second series of tests showed very little change in strength up to 200 deg., but above that point there was a steady continuous fall. Elongation and contraction of area both rose rapidly with the temperature, showing a maximum at 160 deg. for elongation, and at a slightly lower temperature for contraction. The ductility fell rapidly between 250 deg. and 350 deg. A sudden change in the direction of the curves occurred at about 350 deg. The modulus of elasticity showed similar variations to those in the first series.

The fact that the change in the direction of the curves uniformly occurred at the same temperatures appears to indicate that these temperatures are critical for the metal, and such change might therefore be attributed to changes in the phase relationship of the metal; but so far no critical points have been established in thermal curves of similar alloys at the point at which the sudden changes in mechanical properties occurred in these experiments.

The authors therefore infer that the changes in mechanical properties are not related to phase changes in the alloy. They consider that their results are strong evidence of the existence of some kind of cement between the crystalline particles of the metal. At certain temperatures marked slips occur after the yield point is passed, not only with nonferrous metals but also with steel; and sometimes these slips are of such extent that the steelyard falls on the bottom stop as if fracture of the specimen had occurred. But after a short interval the metal recovers and bears a further load.

The authors are of opinion that this phenomenon may be explained by the amorphous cement recrystallizing and causing a reduction of adhesion between the crystals of the metal sufficient to permit some of those crystals to separate from their neighbors under the stress, while actual rupture is prevented by the friction of the crystal faces against each other under sufficient pressure to re-form a quantity of the cement into an amorphous condition, thus partly restoring adhesion.

The reconstituted amorphous material becomes again crystalline by the influence of heat and another slip occurs; so that there are alternate transformations into crystalline and amorphous material, with corresponding decreases and increases of strength. Moreover, during the latter series of tests an appreciable increase in temperature of the gunmetal was observed immediately after each slip; and this is just what might be expected as the result of the recrystallization of the amorphous cement.

### The Strength of Oxy-Acetylene Welds

The same Conference of Shipbuilders and Engineers also brought forth a paper by Prof. A. Campion and Mr. Wm. C. Grey which gave the results of tensile and impact tests of oxy-acetylene welds. The authors remarked that under working conditions the material was usually subjected to repeated shocks; and they had, in addition to static tests, compared the effects of repeated impact on welded and unwelded metal. The material used was mild steel containing about 0.25 per cent of carbon. For the first series bars ⅝ in. in diameter were turned down for a length of 1½ in. at the weld to ⅜ in. in diameter, the elongation being taken on a 1-in. length. Contraction of area was not recorded because most of the fractures were too ragged to allow of measurement. The results indicated that an average weld would have about four-fifths of the strength of unwelded steel, while the ductility would be only about one-fifth. There was no great variation in maximum tensile strength, but ductility varied widely from the average; for, the lowest strength of welded metal was about 80 per cent of that of the original steel, and the lowest elongation was only 9 per cent.

Ductility was increased by hammering; but the strength was lowered. Reheating after hammering improved both the ductility and the maximum stress. Reheating at the same temperature without hammering caused a comparatively large rise in ductility and a small rise in the strength. Quenching in water and reheating brought the strength up almost to that of the unwelded steel but diminished the elongation.

For the impact tests bars 6¼ in. long and ½ in. in diameter were notched in the center of the welded part to a diameter of 0.4 in. The results again showed great variation, and suggested that an average weld would resist only half as much fatigue as unwelded metal. Hammering improves the weld in this respect, but the metal should be reheated at a full red heat—800 deg. C.—to avoid production of strains or brittleness. Reheating or annealing without hammering has but little effect. The treatment which produced the best results in the tensile tests gave the worst in the impact tests.

Further experiments with the bars notched at the edge of the weld instead of at the center were made to ascertain the influence on the whole weld of the overheated zone produced during welding, and the results varied still more than those given by centrally notched bars; but while the hammered specimens of the latter gave 84.4 per cent of the original strength the hammered side-notched bars gave only 57.7 per cent. Impact tests on plates of different thicknesses showed conclusively that the reliability of the weld and the strength decreased as the thickness increased.

The authors conclude that very serious responsibility is incurred by using autogenous welding in parts which may be subjected to any considerable strain.

### Iron and Steel Alloys

Sir Robert Hadfield, in his presidential address to the Faraday Society, remarked that Faraday did a great deal of pioneer work in researches connected with the alloys of steel. He was of opinion, however, that research work on the compounds of iron and carbon had not been sufficiently followed up; and to emphasize the importance with which he regarded such work he offered two prizes of £200 each to the Iron and Steel Institute and to the American Institute of Mining Engineers for the best paper or research on the subject.

Metallurgists were now speaking of carbides, subcarbides, double-carbides and other compounds, but it was most desirable that those substances should be thoroughly investigated and defined. Moreover it was desirable to ascertain the state in which the carbon existed. A certain form of carbon in iron and steel was referred to as a "missing" form, and but little is understood about it; and more information about this form of carbon is required because it was desirable to know whether the carbon not determined as a carbide is "missed" because of its existing in an extremely fine state of division or whether it is in some special form of combination.

With regard to the alloys of iron with elements other than carbon, the fact that in such steel carbon holds a position of supreme importance should not be lost sight of; for with few exceptions its presence in these special alloys was indispensable. For example, in high-speed tool steel, although the carbon content need not be relatively high, yet it must be great enough to ensure the cutting properties of the steel being attained.

As a probable explanation he mentioned that in modern high-speed tool steel there is generally 16 to 20 per cent of tungsten and 2 to 4 per cent of chromium and about 0.74 per cent carbon. Previous to heat treatment the carbon exists in the steel both as carbide and as hardening carbon as defined by Ledebur—0.56 per cent of the former and 0.18 per cent of the latter; but after heat treatment and when the cutting edge of the tool had been brought to the requisite condition, the hardening carbon amounted to 0.6 per cent and the carbide carbon to 0.14 per cent. Consequently the effect of the addition of elements other than carbon must be regarded as entirely due to the change brought about by heat treatment in the form in which the carbon exists by converting it from carbide carbon into what is termed hardenite; and the elements employed as alloys enabled the hardening carbon to retain its properties in a cutting steel. Heat treatment produced a similar change in any low-carbon steel which did not contain other elements except, perhaps, in very small quantities; but the tungsten and chromium in high-speed steel appear to help to maintain the hardenite as hardenite, and consequently the cutting edge did not lose its hardness, even when the friction caused very considerable rise of temperature, such as would soften ordinary steel.

In 1903 he carried out experiments with two kinds of steel, both of which contained similar quantities of chromium and tungsten, but one had a carbon content of 0.35 per cent and the other a carbon content of 0.74 per cent. They were both subjected to heat treatment at 1100 deg. C. and cooled in air, when the steel with the higher carbon content contained 6.6 per cent of hardenite and was an excellent tool steel. The other sample contained practically no hardenite; almost all the carbon existed as carbide; the metal was soft, would not carry a cutting edge and was useless as tool steel.

The importance of investigating the alloys of iron was not to be measured merely from the point of view of getting the exact combination required for any purpose, but also by obtaining the maximum degree of utility from a given quantity of metal. A pound of alloy tool steel would go as far as many pounds of ordinary metal, and although the former was more expensive it was really a saving.

In the United States some 33,000,000 tons of pig iron were now being produced per annum; Germany turned out about 20,000,000 tons, whilst the total output of Britain, France and Belgium amounted to nearly as much more. This enormous consumption of iron ore could not be maintained indefinitely, and we might probably before long find it desirable to husband our resources of iron ore more carefully than we did at present.

Great Britain had now gone down to the third place among the nations in the production of pig iron, but we were more prosperous than ever, and the tonnage production was, therefore, not a decisive index so long as we could maintain a cheap supply of ore, pig or bar iron. But of course the most important point was the provision of the requisite supply of ore. Henri Gaston pointed out in his "Ou va l'Allemagne?" that Germany will shortly exhaust her own supplies of ore and does not control any outside sources of notable value. M. Gaston claims that the metallurgical future of France will be much greater, and he says "We are destined, if nothing happens to counteract our designs, to become the most powerful metallurgical nation in the world."

### The National Physical Laboratory

The annual meeting of the general board was held on Friday, June 19, under the presidency of Sir William Crookes. The work and equipment of the laboratory have made great progress during the past year, and the total value of the goods represented by the materials tested was approximately £300,000. The research carried out by Mr. F. E. Smith on the absolute measurement of the standard of electrical resistance resulted in his finding that the international ohm is equivalent to 1.00052 x 109 C. G. S. units of resistance, or, in other words, the length of the mercury column representing the true ohm should be 106.245 cm., instead of 106.3 cm.

The total income of the laboratory for the year 1913-14 was £43,713 as against £32,058 in the preceding year, and the respective expenditures were £40,968 and £32,479. Consequently the year under review showd a credit balance of £2,745, whilst in 1912 there was a deficit of £420. The experimental tank building fund was deficient to the extent of £2,661, and part of the general balance would be applied to the reduction of this debt.

No doubt from the point of view of the directors of the National Physical Laboratory the increase in their income is very satisfactory; but, having regard to the fact that that increase of income is largely derived from a further diversion of work from professional men in private practice, it is doubtful whether the leading scientific and technical societies will look on the matter with the same degree of satisfaction. The national purse will provide the N. P. L. with all the funds requisite for the carrying out of its legitimate work; and there is no necessity for its entering into competition with the chemist, the metallurgist, the engneer and the electrician.

### Humphrey Pumps for the Egyptian Irrigation Department

The level of Lake Mariut, into which the drainage of the Behira district should flow, has become so much raised that it is no longer possible for the water to adequately make its way into the lake, which has a depth of only about 3 ft. with an area of some 50,000 acres, and which is divided from the Mediterranean Sea by a narrow strip of land having an elevation of 20 ft. or less above the surface of the lake. It has been decided to erect a pumping station at Mex, near Alexandria, for the purpose of discharging into the sea the water from a large canal which is now being cut through the dake. The first installment of the plant will consist of ten Humphrey pumps capable collectively of delivering 980,000,000 of gallons of water in 24 hours, with a lift of about 20 ft.; but two pumps will be kept in reserve. It is proposed to add another set of ten similar pumps afterward. The combustion chambers of these pumps will have a maximum diameter of 8 ft. 8 in. and a height of nearly 14 ft., while the water valve boxes will have only half that height with the same diameter, and will each be furnished with 100 hinged valves of new design. Each of these pumps will have about two and a half times the capacity of the large Humphrey pumps at the Chingford station of the Metropolitan Water Board. They are being constructed by two British firms.

Power will be supplied from an anthracite Mond gas plant gassifying 44 tons per day with a guaranteed consumption of 1.15 lb. of coal per water horse-power.

An electric power and lighting plant will also be put down consisting of two 180-b.h.p. gas engines coupled directly to 120-kw generators supplying current at 220 volts.

### The Institute of Metals

### The Employment of Non-Ferrous Metals in the Navy

Sir Henry J. Oram, engineer-in-chief of the fleet, in the course of his presidential address to the institute, gave some very interesting figures relating to the amount of non-ferrous metals used in the construction of our battleships and cruisers at the present day as compared with 20 or 25 years ago.

At the present time for every hundred tons of iron and steel used in the construction of a battleship there were about six tons of copper or copper alloys, whilst in a cruiser the proportion of copper and its alloys amounted to eight tons. The higher proportion of non-ferrous metals used in the construction of a cruiser was owing to the smaller weight of armour carried and the increased power of the machinery which, of course, necessitated the employment of a proportionately greater amount of non-ferrous metals than did the hull and other structures.

With regard to the propelling machinery, the proportion of non-ferrous metals in a modern battleship was some 17 per cent of the steel and iron. Twenty years ago the corresponding proportion of non-ferrous metals was some 34 per cent.

The proportionate amount of non-ferous metals, however, had not been similarly reduced in the structure of the hull, and the greater increase in the employment of steel had been counterbalanced by the large increase of non-ferrous metals employed in gun turrets, controlling apparatus, electric lighting and so on, so that excluding the propelling machinery the whole structure of a battleship now contained about 4.4 per cent of non-ferrous metals in relation to the amount of iron and steel, as against 4.2 per cent 20 years ago.

A great deal of careful attention had been given to condenser tubes, which simple articles had an important effect on the reliability of the ship's machinery. Corrosion of condenser tubes constituted a very important defect but some of the worst troubles experienced in the navy have arisen not so much from corrosion or perforation as from splitting of the tubes whilst at work and although the total failures due to corrosion and perforation largely exceeded the number due to splitting, the consequences of the latter mishap were very much more serious. In the year 1908 there were approximately 2,500,000 condenser tubes in use at sea in the fleet, and the number of failures reported as having occurred on service were: splitting 21; corrosion and perforation 69; giving a total of 90, which was equal to one tube failing in 28,000 for the year.

The 1913 returns showed approximately 3,800,000 tubes in use, and the total number of failures reported as having occurred during the years 1912 and 1913 were: splitting 16; corrosion and perforation 115; giving a total of 131, which was equal to one in 60,000 per year, which figures showed a very satisfactory reduction.

### Company Meetings and Results

*John Brown & Co. Ltd.*—Lord Aberconway presided at the annual meeting on June 30, and remarked that he considered the balance sheet to be the best and strongest ever presented by the company. The balance amounted to £467,000; out of which, after paying the usual preference dividend and 10 per cent on the ordinary shares, £100,000 would be appropriated to extensions and £96,000 carried forward to next year's account.

*General Electric Co., Ltd.*—The ordinary general meeting was held on July 2, when Mr. Hugo Hirst presided. The net trading profit for the year was £157,893, and the total balance was £190,224. After due provision for depreciation, placing £30,000 to reserve account, and putting £14,000 toward the expenses of the recent increase of capital, this sufficed for a dividend of 10 per cent on the ordinary shares and to carry forward £36,739.

*Victoria Falls and Transvaal Power Co., Ltd.*—The annual general meeting took place on July 8 under the presidency of the Marquess of Winchester. For the year 1913 £467,823 were carried to appropriation account, £21,443 more than in the previous year. Interest on debentures absorbed £203,920; £135,491 were applied to depreciation, and £128,411 carried to credit of profit and loss account which showed a balance of £225,198, out of which dividends at the rate of 6 per cent per annum had been paid on the preference shares for the year 1912. The dividends amounted to £120,000, leaving £105,198 to the credit of profit and loss account as a reserve at the beginning of the year. It will be seen that the preference dividend is twelve months in arrear.

*Mond Nickel Co., Ltd.*—Sir Alfred Mond presided at the annual general meeting on July 6. A number of new properties had been acquired and developed during the year. The profit and loss account showed a balance of £297,000 against £232,000 for the previous year. After deducting the amount of the interim dividend on the preference shares the available balance was £284,000.

The directors proposed to pay the usual dividend on the preference shares, 35 per cent on the ordinary shares, a dividend of £79,000 on the deferred shares, and to carry forward £91,000.

*Brunner, Mond & Co., Ltd.:*

The report for the year ended March 31st shows a profit of £769,344. O. O. It is proposed to pay a dividend on the ordinary capital amounting, with the sum paid on December 12th, to $27\frac{1}{2}$ per cent for the year, less income tax. £2,500 O. O. is written off patents account and £110,921 O. O. is carried forward.

*The Bleachers' Association:*

The account for the year ending March 31st shows a net profit of £666,045 O. O., after placing £210,865 O. O. to repairs and maintenance account, £15,000 to leasehold and sundry property account and £60,000 to depreciation. £50,000 will be transferred to general reserve, £60,000 to reserve for equalization of dividends and £15,000 to fire insurance.

A dividend for the six months ended March 31st of 7 per cent on the ordinary shares is recommended, making 6 per cent for the year. £173,957 is carried forward.

### Market Prices

### *July*, 1914

| | £ s d |
|---|---|
| Aluminum, ingots, ton lots | 86. 0. 0 |

## Concentrating Unsized or Unclassified Ore-Pulp

A new ore-concentrating machine having the general appearance and mode of operation of a concentrating table, but acting more on the principle of a jig, is the Isbell concentrator, manufactured by the Denver Engineering Works Co., Denver, Colo. The device is a radical departure in concentrator construction, and embodies some novel features in its operation. Preliminary classification or sizing is dispensed with; there is no transverse current of wash water; concentrate pockets deliver the concentrate through the deck of the table, while tailing and middling pass over the end; the general movement of ore-pulp is coincident with the progressive motion of the table.

A view of the concentrator from the tail end is shown in Fig. 1. It consists of a riffled deck divided into two similar sections by a longitudinal partition, each section having a feed-box, riffles and six concentrate pockets which are supplied with hydraulic water from above. The deck is mounted on steel base-frame and steel spring supports, and carries the concentrate launders underneath. The drive imparts a differential reciprocating motion to the deck. The riffles converge from the edges of each section to the central line of concentrate pockets, and their use is mainly to direct the stratified concentrate to the pockets. A section through one of these pockets is shown in Fig. 2. In a measure it constitutes a classifier, inasmuch as the hydraulic water flowing against the entering stratum of concentrate effectually sorts and washes back any gangue particles that may be included.

The operation of the concentrator is unusually simple. Ore is ground to, say, 6-mesh, and without classification or sizing or removal of slime, is fed onto the reciprocating deck of the table with enough water to make the pulp flow readily. The motion of the deck causes the particles of pulp to stratify according to their relative specific gravities, and the heaviest mineral particles settle into the riffles, with the gangue lying above. As the pulp progresses along the deck the settled concentrate is directed by the riffles into one of the concentrate pockets where it encounters a light stream of water under pressure sufficient to wash back any gangue, while allowing the concentrate to enter and pass out through the discharge tube. Any valuable mineral that does not settle and pass into the first pocket is caught in one of those farther down the table. The gangue flows over the pockets. Finally, anything passing the last pocket is presumably either middling or tailing, and these are separated by the last set of riffles and divided on the tail board by means of adjustable partitions.

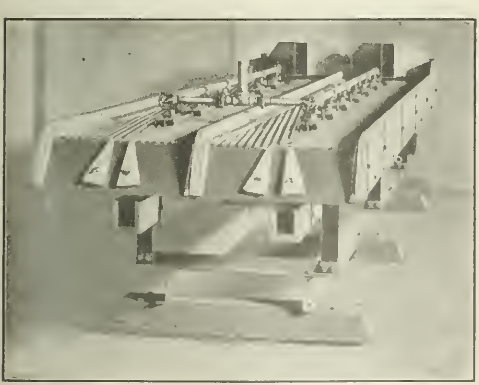

FIG. 1—ISBELL CONCENTRATOR

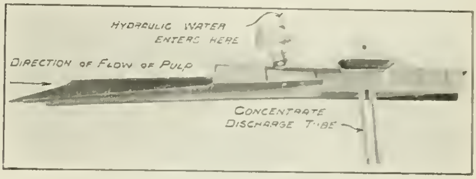
On a machine of this type the practice of treating an unsized or unclassified feed is not as unorthodox as it sounds. It is well known, for instance, that the motion usually appllied to a gold-pan filled with coarse and fine ore and water results in gathering all heavy mineral or metal in a bottom layer, irrespective of the size of those particles. Similarly, the Joplin jig treats an unsized product, with the result that practically all the free mineral settles through the pulp, the coarser particles being retained on the bed, while the fine pass through it into the hutch. In the same way the unsized pulp fed onto an Isbell concentrator becomes stratified, and all heavy particles, irrespective of size, accumulate in a bottom layer that is subsequently guided by the riffles into the pockets and discharged. By regulating the stream of hydraulic water entering the pockets, the concentrate may be discharged with a varying quantity of gangue.



HYDRAULIC WATER ENTERS HERE
DIRECTION OF FLOW OF PULP
CONCENTRATE DISCHARGE TUBE

FIG. 2—CONCENTRATE POCKET ISBELL CONCENTRATOR

A number of advantages are claimed for this new concentrator. It has a large capacity, ranging from 50 to 100 tons per 24 hours, due to the method of handling the ore in a deep bed, and the separation of mineral from gangue by jigging action without the use of a transverse current of wash water. Preliminary sizing is unnecessary, and the usual devices for this work can be omitted from the mill system. Fine or slime mineral is readily recovered as long as it is treated with the coarse. The machine requires about the same power as do ordinary concentrating tables. The quantity of water required for regulating the action of the concentrate pockets varies from 7 to 15 gal. per min., under a head of about 15 ft.

## The Application of Cold, Cleaned Producer Gas to High-Temperature Regenerative Furnaces

Under this title Mr. H. F. Smith, general manager of the Smith Gas Power Company of Lexington, Ohio, has published an interesting bulletin on this company's system of generating and distributing producer gas.

In order to characterize first some general features of this system, it may be said that the Smith producer is a mechanically operated suction producer. The shell, lining, and other heavy parts are stationary, and the agitation of the fuel bed is attained by the movement of the grate bars. A centrally located gas outlet is provided which prevents channeling along the producer lining. In conjunction with this is a magazine feed. The grate area is ample so that the rate of gasification is moderate and the production of high temperatures is avoided. The grate surface is large and concentration of the blast at this point is avoided. The ash-pit space beneath the grate is segregated, permitting the distribution of the blast to various parts of the fuel bed to be accurately controlled. The stoking mechanism is also segregated so that the stoking action can be accelerated over any portion of the fuel bed.

Smith producers are provided with the saturator system of vapor control about which more will be said below. The gas output is automatically controlled as to volume and quality and the manipulation of the producer is entirely independent of any conditions that may be imposed at the furnace by the furnace man.

Smith gas is cleaned and cooled before being delivered to the gas mains. The volume of gas to be handled is only about one-fourth that issuing from hot gas producers from the same volume of fuel. The gas may, therefore, be distributed through small unprotected steel pipes. There are no deposits in the mains. While the gas is cooled and cleaned, this is claimed not to involve any loss in thermal efficiency from the precipitation and removal of tar, since provision is made whereby the waste heat contained in the discharge gases from the producer is utilized in converting the tar into fixed gas. With the Smith system both ammonium sulphate and tar can be recovered in marketable form if desired.

Finally a high efficiency is claimed for the Smith producer. "While there is apparently a loss of heat units resulting from the cooling of the gas, this loss is for practical purposes more apparent than real and in regenerative furnaces Smith gas will produce a greater heating effect per pound of coal than can be produced from the same quantity of fuel when gasified in the so-called hot gas producer." This statement will probably meet with opposition, and it will, therefore, be interesting to analyze later Mr. Smith's argument in favor of this claim. But we may first discuss the technical principles by which uniformity of gas quality is obtained in the Smith gas producer. It is based on three principles, (*a*), (*b*) and (*c*).

(*a*) Maintenance of uniform ratios between air and water vapor in the blast to the producer. This is obtained by the use of the "saturation system" in which the air supply to the ash-pit is preheated and saturated with water vapor by being brought into contact with large surfaces of hot water. "With the Smith saturation system not only can the presence of an excess of vapor in the blast be entirely prevented, but any excessive amount of moisture in the gas, from any cause whatever, either through firing of wet fuel, through the liberation of contained moisture from the coal, or from the passage of undecomposed steam through the fuel bed, will be removed by the subsequent cooling of the gas which causes a condensation of any excess of water vapor from whatever source. Accordingly, with the Smith system, the delivery of excessive amounts of vapor to the furnace with the gas is absolutely prevented."

(*b*) Maintenance of uniform rates of distillation of hydrocarbons from the coal. To obtain this in the Smith producer, the fuel supply is uniform from large fuel magazines above the active fire zone into which coal can be discharged as required without producing any disturbance of the gas-making conditions whatever. The fuel descends into the gas-making zone only so fast as the coal below is consumed and in this way sudden fluctuations in the hydrocarbon content of the gas is avoided.

(*c*) Maintenance of uniform temperatures and ample time of contact between the fixed carbon and the blast in the body of the producer. This is obtained by the large grate surface provided and a moderate rate of driving the producer.

The chief novelty of the whole system is to be found, however, in the use of a cold, cleaned gas in the Smith system as against the usual hot producer practice. Naturally Mr. Smith pays considerable attention to this point in his pamphlet. For the purposes of this review it may be considered from three different viewpoints: efficiency of generation of the gas, of its distribution, and of its utilization at high-temperature regenerative furnaces.

### EFFICIENCY OF GAS PRODUCTION

With respect to the *generation of the gas* in the Smith producer the energy balance sheet would show (1) a useful consumption of energy. "The efficient production of gas by the producer process is dependent upon the carrying out of a number of *heat-absorbing* reactions within the fuel bed." The gas in leaving the producer carries with it chemical energy which becomes available in form of heat when the gas is burned with air. (2) Losses in form of unburned carbon in the ash, in form of heat loss by radiation from the producer walls, and in form of sensible heat carried out of the producer by the gas.

Losses in unburned carbon are reduced to a minimum by providing a large grate surface and by a slow rate of driving the producer.

This slow rate of driving also makes it possible "to carry out completely the chemical reactions involved in gas making without carrying the temperature of the fuel bed above very moderate figures." Further the central gas outlet tends to divert the blast from the producer lining so that excessively high temperatures in the latter are avoided and the radiation loss from the producer walls is reduced.

"The most important source of heat loss from the producer is the heat carried over by the discharge of the gases at high temperatures. At this point is wasted not only that unavoidable portion of heat which represents the temperature at which the fuel bed must be maintained for proper working, but also the additional heat losses which results from imperfect and incomplete chemical actions of all sorts within the producer itself. . . . The most direct index, therefore, of the efficiency with which the various chemical reactions in the producer are carried out is the temperature of the gas discharged from the machine. If these reactions are complete a maximum amount of heat will have been absorbed and its energy converted into latent chemical energy in the gas. On the other hand, if the reactions are incomplete, this fact will be indicated invariably by waste of heat which results in higher gas temperature."

At the Alton plant using a Smith producer the average temperature of the discharged gases is between 750 and 800 deg. F. At the Smith Gas Power Company's factory the average temperature of the discharge gases at the point of leaving the producer shell is from 350 to 555 deg. F. Both temperatures are much lower than in usual hot gas producer practice. If an average value for the latter is taken as 1600 deg. F. and the temperature of the exit gases in the Smith producer as 700 deg. F., Mr. Smith figures that this temperature difference of 900 degrees represents a loss of 1620 B.t.u. per pound of coal—quite an appreciable loss.

The whole argument of Mr. Smith is decidedly interesting. It would be very illuminating to get for comparison an exact numerical energy balance sheet for the Smith producer and for a hot gas producer, with detailed analyses, temperature records, etc. There is surely no flaw in the argument that *if everything else is the same*, except the temperature of the gases leaving the producer, the producer with the lower gas temperature is the more efficient one.

But a few questions would seem to suggest further investigation. If we keep the temperature in the producer purposely down, how do we change thereby in detail the chemical reactions? The final net result seems very satisfactory, as indicated by the composition of Smith producer gas, given as the average of five analyses made at different times at different plants, using different grades of bituminous coal: 5.2 per cent $CO_2$, 0.9 $O_2$, 25.0 CO, 4.3 $CH_4$, 14.6 $H_2$, 50.0 $N_2$; per cent combustibles, 49.9; average heating value, 172 B.t.u. per cubic foot.

Another question is this: Is not the efficiency of the gas producer, taken for itself, only a matter of purely theoretical interest? Is not the important matter from a practical standpoint a high efficiency of gas production and utilization combined? For the sake of utilization in the regenerative furnace, is it not better to have hot gas? This is certainly a pertinent practical question. Mr. Smith's answer to it will be found below under the heading: Utilization of Gas in Furnace.

### DISTRIBUTION OF GAS

That for distribution purposes cold gas has decided advantages, is evident. The volume is so much smaller and the distributing flues may be made correspondingly small. The gas having been cleaned is free from impurities which would block up the flue and would require to be periodically removed.

But Mr. Smith points out another advantage of purely chemical nature which is liable to be overlooked. "Cold producer gas remains unaltered in composition and is delivered to the furnace in exactly the same physical and chemical state as when generated at the producer. This is by no means true of hot gas," on account of the liability of carbon monoxide decomposing into carbon dioxide and free carbon (forming soot), or of the reaction between methane and water vapor, resulting in the production of carbon dioxide and the liberation of hydrogen. Such reactions reduce the heating value of the gas per cubic foot.

### UTILIZATION OF GAS IN FURNACE

"It has been commonly assumed that the thermal energy delivered to a regenerative furnace by the heat carried in hot producer gas contributes directly to the furnace efficiency. Recent careful investigations along this line have indicated that this is by no means universally true. It has been shown both from theoretical considerations and by practical tests that the direct and immediate effect of delivering hot producer gas to the checkers of the regenerative furnace is *to raise the temperature of the stack gases* of the furnace. . . .

"The amount of heat present in the producer gas as sensible heat must certainly be wasted at one point or another. Either it may be removed from the gas at the producer and taken up again in the regenerators at the furnace, with a corresponding lowering of stack temperature, or it may be carried into the regenerators with the producer gas with a corresponding increase of the stack temperature. In either case nothing whatever is contributed to the temperature of the hearth in this way.

"It has been pointed out that by cooling the producer gas, tar and other combustible constituents are precipitated from the gas and lost. This is not by any means the case in the Smith system, since this tar is completely fixed and gasified in the producer, the waste heat contained in the outgoing gases being utilized for this purpose. There being no direct loss in plant efficiency from cooling the producer gas, it remains to be shown that there may be gains in furnace efficiency incident to this process. These gains undoubtedly do exist." First, there is the precipitation of any entrained moisture which would represent a loss and a disturbing element in the furnace operation. Further the process insures more uniform gas quality.

In addition, "with cold gas distribution the supply of gas to the furnace is absolutely and directly under the control of the furnace operator. Small valves of ordinary construction will positively regulate the flow of gas and this will be independent of conditions of stack draft at the furnace or any condition imposed by the requirements of producer operation.

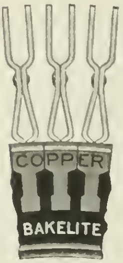
"The aggregate gain to be anticipated from all of the advantages will depend to some extent, of course, on the expertness with which the two types of apparatus are manipulated."

## Bakelite for Commutator Insulation

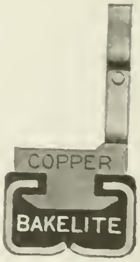
To find out the actual as well as the relative strength of auto starter and lighter commutators, the U. S. Light & Heating Company, of Niagara Falls, recently carried on several tests. The last commutator tested gave by far the best results. This commutator with bakelite molded insulation, proved practically indestructible; it was speeded up to 9060 r.p.m., or 24,600 ft., per minute peripheral speed before going to pieces. As the maximum speed at which such a commutator would be operated in service is only 3500 r.p.m., the factor of safety in the above instance would be 6.7, since the force tending to break the commutator varies as the square of the speed.

COMPLETED COMMUTATOR

It is interesting to compare this test with the previous tests made by this company on commutators made up of brass and steel rings with mica between rings and bars. These constructions proved inferior to the bakelite commutators for the brass commutators went to pieces at 6000 revolutions, while the steel commutators would stand only approximately 8000 revolutions.



CROSS-SECTIONAL VIEW



LONGITUDINAL SECTION, SHOWING INSULATION

Since this test was made there has been a slight change made in the design so that the U. S. Light &

Heating Company are of the opinion that their bakelite commutators will stand 10,000 r.p.m.

The type of commutator tested is shown in the accompanying illustrations, the sections showing the construction of copper segments, steel rings, and bakelite insulation. The commutator complete weighs 8.46 lb., and has an outside diameter over the tangs of $13\frac{3}{8}$ in. When tested, the tangs were removed so that the commutator then weighed 7.06 lb. and had an outside diameter of $10\frac{3}{8}$ in. This is the diameter at the commutator face.

In order that the commutator, while being tested, would approach service conditions as to temperature, it was heated up to 265 deg. Fahr. before testing; this temperature being higher than would occur in service. Calculations show that the disrupting forces, that is, the force tending to pull the commutator apart, was 15,230 lb. per sq. in. As this was resisted by the tensile strength of the steel rings and bakelite molded insulation, the holding power of the bakelite and steel rings is evidently equal to this figure.

In addition to having the high tensile strength for commutator insulation, bakelite possesses other qualifications; it has high dielectric strength, will not soften under heat up to at least 400 deg. Fahr. and is impervious to oil and moisture.

---

## A Fume and Smoke Recorder, Monitor, and Precipitator, and an Instantaneous Thermostat

BY W. W. STRONG.

During recent years great advances have been made in our knowledge of the electrical properties of gases with the result that a number of new electrical instruments have been developed in connection with furnace operations. An illustration is the electrical precipitator* for removing fumes and smoke from gases. A new type of apparatus is the fume, dust and smoke recorder and monitor.

### The Recorder

The fume, dust and smoke recorder is an apparatus designed to register the amount of fumes, dust or smoke in gases. At the same time it may be made to automatically regulate other kinds of apparatus. The mode of making records may include the plotting of a curve on a paper drum or integrating the total time that fumes or smoke of a given density have been emitted.

In the case of smoke many city ordinances permit a few minutes (say six) of smoke emission per hour. The integrating recorder gives the total time in a given interval that the stack has emitted smoke exceeding a certain density. The stack may smoke 3 minutes now, 7 minutes later, 8 minutes later, etc., and the recorder is adjusted so that a watch or clock runs during the smoking periods. In the above example it runs $3 + 7 + 8 \quad 18$ minutes.

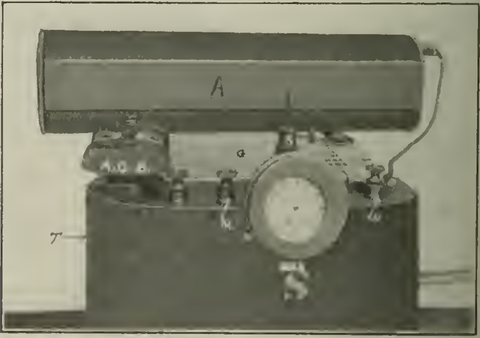
The watch or clock face can be placed so as to be seen by the furnace operator so that he knows what the character of the fume or smoke emission of the furnace stack is at any time. The recorder may be of a portable or stationary type.

The operation of the fume and smoke recorder is very simple. An electrical discharage is given the opportunity of either flowing between electrodes forming an air-gap in the fume or smoke stack or flowing into a condenser and charging it. In the figure a portable recorder is shown. The main part of the apparatus is a step-up transformer T of small current-consuming capacity. The terminals of the transformer are connected in parallel to the stack gap and a condenser in the upper part of the apparatus. By proper setting the condenser is charged whenever the fumes or smoke in the stack exceeds a certain predetermined density depeneding on the length of the gaps. When the condenser is charged the watch or clock is started. In the figure the watch is shown. The only adjustment to be made is that on a spring S holding one of the condenser plates.

It is thus seen that the fume and smoke recorder is very simple in operation, contains no moving parts except the watch and the lever which starts and stops the watch. M and N are binding posts which can be connected to any 110-volt 60-cycle lamp socket. The energy consumed is about 80 or 100 watts. No chemicals are used. The apparatus can be placed in any convenient place and requires practically no attention.

### The Monitor

The fume and smoke monitor is essentially the same in its action as the recorder with the difference that in this case an electric circuit is opened or closed instead of a watch being started or stopped. In this way bells, lighted signs and other indicating apparatus may be operated. The value of the monitor lies in part in the fact that its action is instantaneous so that the furnace operator can immediately remedy conditions. In the case of a coal furnace the firemen can immediately change the conditions so that smoking shall cease.



FUME, DUST AND SMOKE RECORDER

In the figures A C B is a bell which attracts attention to the illuminated sign A. This sign is behind a crown glass screen and contains the lettering "Fuming" or "Smoking" and any suitable directions. The figure represents a combined portable monitor and recorder.

In the case of the monitor the only part requiring any attention is that of the contact points held by the spring S. As the contact points wear away the spring should be slightly lowered. By using tungsten or similar metal the wearing away of the contact points is small.

### The Precipitator

The writer has developed a method* of precipitating any kind of fumes, dust or smoke by the use of an electrical corona discharge. This method is probably the most efficient way of precipitating fumes, dust and smoke under many commercial conditions. In the above figure the apparatus can be used so as to precipitate the fumes, dust or smoke if the quantity of

---

*See Proc. A. I. E. E., June 27, 1913, *Journ.* Franklin Inst., Sept., 1912.

**Journ.* Franklin Inst., Sept., 1912. Proc. Am. Inst. Elec Eng., June 27, 1913.

gas is small. An instrument of this type will handle in the neighborhood of 80 or 100 cu. ft. of gas per minute. An instrument of this kind is very convenient for precipitating any kind of fumes or smoke in small quantities. Very fine smoke such as cigarette smoke is precipitated beautifully.

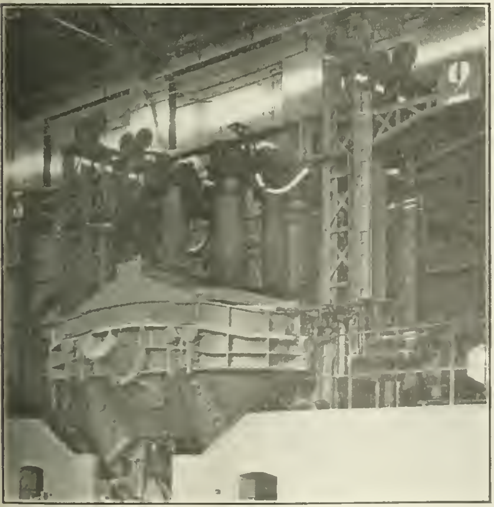
### An Instantaneous Thermostat

In the case of ordinary thermometers, thermopiles, pyrometers, etc., there is a certain degree of sluggishness. This sluggishness is greatly increased by the fact that the active thermal detecting parts are usually enclosed in a protecting case which is more or less heat-resisting. In the case of my recorder and monitor there is no case of any kind about the "stack" electrodes so that the recorder or monitor indicates almost instantaneously when the conditions in the gap change.

Under certain conditions as, for example, the intermittent existence of flame or hot gases in the gap, the monitor apparatus can be adjusted to act as a practically "instantaneous" thermostat. The sensitiveness and quickness of action of purely electrical circuits is well known and as the flame or hot gas is the region through which the electrical discharge itself takes place it is easily seen how nearly instantaneous its action can be.

## Electric Steel for the French Army and Navy

The Cie. des Forges & Acières Electriques, M. Paul Girod, at Ugine, Savoie, France, is reported to be working busily day and night its large electric furnace plant for the production of special steels for the French army and navy. The accompanying illustration shows the latest addition to the steel-making equipment of this plant. It is a Girod furnace capable of melting up to 25 tons of cold charges of scrap iron and steel.



TWENTY-FIVE-TON GIROD ELECTRIC STEEL FURNACE

The plant has been remodeled and now contains two Girod electric furnaces of $2\frac{1}{2}$ tons capacity each; two Girod furnaces of 10 to 12 tons capacity each, and one furnace, as shown above, with a capacity up to 25 tons of cold charge.

A separate plant in the same town produces large quantities of ferro alloys by means of the electric furnace process.

## Suspension Type Storage Bins

The design of storage bins for ore and similar material is an item in mill and smelter construction that requires more careful consideration than it sometimes receives. Efficiency and economy in operation require that such bins should discharge their contents readily without resort to shoveling or mechanical means for emptying them; and the design should take into consideration the angle of repose unit weight and size of the material to be handled. The first cost of the structure should be as low as possible but should not be sacrificed to low cost of maintenance; neither should the structure be subject to heavy depreciation.

A storage bin embodying these ideal features is the Baker suspension type manufactured by Arthur G. McKee, of Cleveland, O. As shown in Fig. 1 the bin combines the principles of the suspension and hopper types, the suspension principle being utilized in the support of the structure and the hopper in the design of the bin bottom. This combination makes possible a slope of sides and bottom greater than the angle of repose of the contents, thus insuring free flow and complete discharge.

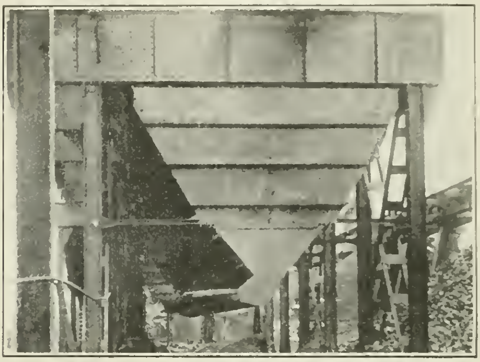


FIG. 1—SUSPENSION TYPE STORAGE BINS

A variety of materials can be used in the construction of these bins—wood, concrete or steel, or a combination. The suspension rods and bottoms are built in interchangeable units, thus facilitating erection. One type of bin lining, suitable for coal and ash, is concrete laid on asbestosteel, which is sheet metal with a protective coating of asphaltum covered with asbestos. In another type, concrete slabs $2\frac{1}{2}$ to 4 in. thick form the lining. Wooden lining also may be used for suitable purposes.

For the storage of ore and similar abrasive materials, the bottoms are of steel throughout, made in unit lengths equal to the spaces between supporting bents. The discharge outlet is continuous for the entire length of the bin, and the discharge of material is governed by a continuous series of quadrant gates that may be operated mechanically or by hand. The space beneath the bins is unobstructed, and is available for handling the discharged material. The entire design is flexible, and the bin may be enlarged by adding new units.

**The Bristol Company**, of Waterbury, Conn., celebrates this year the twenty-fifth anniversary of its foundation. Its plant has grown at the rate of doubling the floor space once every five years. The growth of the business has been especially large during the last six years, since in 1908 the president of the company, Mr. Wm. H. Bristol, again took up the general management.

## An Adiabatic Calorimeter

The calorimeters in general use are subject to many errors, namely those of radiation through the surrounding wall, of conduction through the metallic parts and the thermometer, and those due to the inaccuracy of the thermometer readings.

The following description of the Riche adiabatic calorimeter deals with an attempt to eliminate all these errors, through the use of a *vacuum cup* with a suitable covering, proper precaution having been taken to insulate the different parts.

*Description of Apparatus.*—In all calorimetric work the rise in temperature, multiplied by the quantity of water affected, gives the calories directly, provided there is no loss or gain in heat. Fig. 1 is a sectional sketch of the bomb and calorimeter, which has been designed. It consists of a bomb, *a*, which may be of any type; of a vacuum cup, *b*, containing water; a stirrer, *j*, and a thermometer, *T*. The stirrer is of the screw propeller type, which is very efficient. The vacuum cup is of standard size, 14 cm. wide, 30 cm. high, inside measurements, and was obtained through the Vereinigte Fabriken f. Laboratoriumsbedarf, Berlin, Germany.

The bomb is of the Mahler-Kroeker porcelain type and should last for 8000 combustions; and, inasmuch as it has two outlets, 4-5 determination of carbon may be made. The support for the bomb is a hinged ring, *c*, supported by two brass rods connected with the cover. The rods are insulated by passing them through hard rubber, *m*, and a hard rubber cap is screwed on the end of each rod.

To prevent any possible heat loss from the vacuum cup, it is surrounded by an oak box, *w*, lined with 1-in. pressed cork, *o*, glued to the wood. On the cover, in addition to the cork, is glued a piece of hair felt, *f*, ½ in. in thickness, effecting a tight joint with the top of the vacuum cup.

A hinged door in the front facilitates the handling of the vacuum cup and the cover is raised and lowered by means of telescope tubes, thus giving opportunity to place the bomb in the split ring and to adjust the ignition wires. After the cover is lowered the thermometer is placed in position through a hole in the cover, into which is screwed a brass tube to support and protect it.

*Method of Making a Combustion.*—The substance to be burned is prepared, weighed and placed in the bomb, which, after being charged with 30 to 40 atmospheres of oxygen, is then placed in the split ring and the wires connected. The water in the vacuum cup is brought to any temperature within plus or minus 5.0° of the room temperature, the cup is then placed in position, the door closed and the top lowered. The thermometer is adjusted and the motor started. Readings are then taken until the temperature of the water becomes constant. The heat absorption is complete when the thermometer shows a constant temperature for three successive minutes.

Temperature equilibrium having been established, the bomb is removed, opened and rinsed with water, and the rinsings are titrated with one-tenth normal alkali for nitric acid, using litmus as an indicator.

*Method of Ignition.*—Ignition of the substance in the bomb is accomplished by a current from three two-volt storage cells, which first passes through a 3-ampere fuse wire, in series with a platinum wire within the bomb itself. The platinum wire is connected with the substance to be burned by means of a linen thread of sufficient size to secure ignition. The fuse assures the constancy of the heat ignition.

*The Need of Exact Determinations.*—Whereas other types of the calorimeter require frequently repeated readings and a consequently complicated system of calculations because of imperfect insulation, the Riche calorimeter needs only minute readings. It requires from three to five minutes for the temperature of the water to become neutral and stationary. The operator may ignite his material and then do anything that he pleases during the short interval that follows the final reading.

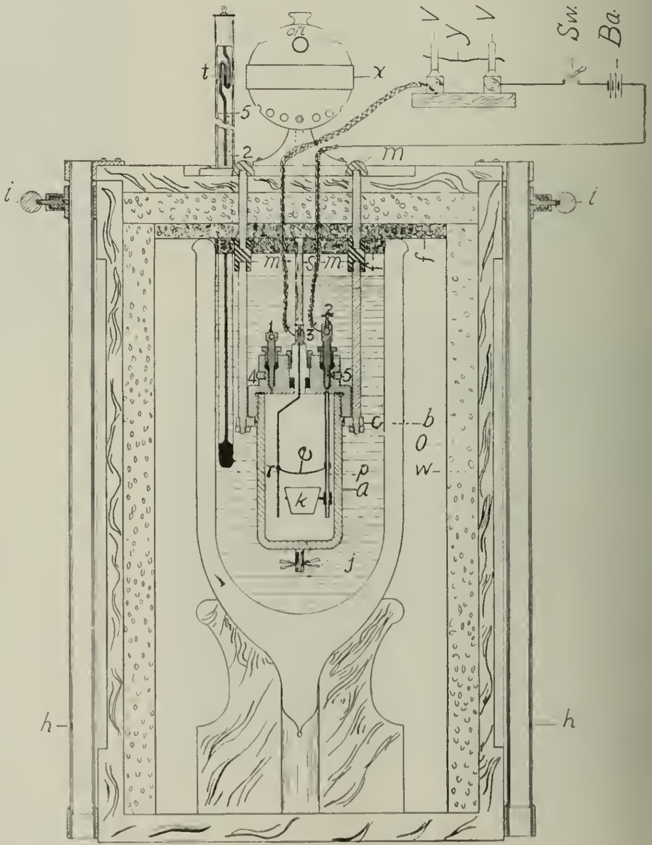

FIG. 1—ADIABATIC CALORIMETER

*Calculation of Results.*—The reading at ignition is taken as the initial reading. This subtracted from the final reading gives the total rise. This rise multiplied by the weight of water (plus the hydrothermal equivalent of the apparatus) gives the total number of calories liberated. From this is taken the heat resulting from the ignition, and the nitric acid formed. This result, divided by the weight of substance, gives the calories for the unit of material oxidized.

The Riche calorimeter, therefore, saves from 50 to 75 per cent. of the operator's time. To this saving of time there is added the perfection of the entire calorimeter device. The calorimeter as an established laboratory device will soon be employed generally in connection with the large consumption of all fuels, foods and commercial products, the value of which depends upon their heat contents.

---

## The Metal Spray Process

The Schoop spray process for the production of metallic coatings is well known to our readers from two articles of the inventor, Mr. M. U. Schoop in Zurich, Switzerland, published in our Vol. VIII, p. 404, (1910) and Vol. XI, p. 89, (1913).

The process has naturally been the subject of much speculation and inquiry since it appeared in Europe. Its recent improvements, now protected in the United States, and the acquiring of rights for this country by the Metals Coating Company of America, People's Gas Building, Chicago, make it possible for us to publish some further details of its commercial applications.

The corporation now owning all the United States rights of Schoop and other European inventors already possessed the basic patent, which controls impacting of metal irrespective of the nature of the apparatus used, and the company is therefore in a position to utilize in metal spraying a group of inventions no one of which would have sufficed for the present stage of commercial development which the process has attained. Mr. John Calder is the president of the Metals Coating Company of America.

As described in detail in Mr. Schoop's former articles, the principal apparatus used in the spray process is a "pistol." Into one side of it a cold metal wire on a reel is pulled in continuously at a uniform rate. Within the pistol the metal wire is melted by a hydrogen-oxygen flame and by means of a violent air-blast the melted metal is "fired" out of the pistol in form of a very fine spray at a very high velocity.

If the nozzle from which the metal spray issues is pointed from a distance of 5 in. at the surface of various objects of metal, wood, paper, stone, clay, cement, cloth, silk, glass and other substances, the surface receiving the spray becomes coated with a dense adherent film of the metal composing the wire fed into the pistol. Elemental and alloyed metals may be handled with equal facility. Lead, tin, zinc, aluminium, copper, brass, bronze, German silver, etc., may be fed into the instrument at will and deposited freely in coatings from 0.001 in. upward in thickness.

The temperature of the molten metal spray at the nozzle may be varied according to the wire used from 700 deg. F. to 2000 deg. F., yet 5 in. away none of the objects coated is injured or altered in the act of metallizing them. Matches held in the zinc spray are immediately coated over without ignition, and the thinnest paper and wood receive the impacting particles into their pores without charring. Brass issuing at 1550 deg. F. from the nozzle is deposited on the thinnest silk fabrics without damaging the textile.

In considering what occurs in the Schoop process it is necessary to bear in mind a singular fact: the sprayed metal moves only 6 in. between its points of fusion and the object to be coated, yet it does *not* reach the object in a molten state. It even possesses so low a temperature that it can be safely directed upon the hand for a moment without injury and can be continuously impacted upon materials such as cloth, paper, wood and even celluloid, which would be immediately consumed by the heat of any molten metal. A box of matches can be coated all over to form a seamless metal case without a single match being ignited.

The reason is that the gaseous medium used is much larger in volume at any moment than the drop it has pulverized and is carrying and the gas is expanding so rapidly that its temperature is far lower than that of the spray. A rapid exchange of heat therefore takes place between them which consolidates the molten particles and gives them a temperature far below the melting point. If the particles arrived in a liquid state at the base with the observed velocity of 3000 ft. a second they would simply splash on the plate and largely rebound. As a matter of fact they impact and interpenetrate freely and the later bombarding particles unite with the earlier ones to form homogeneous compact bodies. In accounting for the observed action of the Schoop spray at the receiving base, it is supposed that the cooled particles of metal just before impinging with great velocity on a hard surface are in an abnormal physical condition. Due to the heat of collision they pass directly into a vapor which condenses and solidifies on the relatively cold receiving body, penetrating by osmotic pressure the superficial pores of the base where any affinity for the latter exists and, otherwise, driven in by the pressure behind it.

In either case it condenses and solidifies after penetration and is effectively dovetailed into the base. The hammering and bombardment of the solidified first coat by the minute succeeding particles is practically a process of cold working. The entrained particles liquefy and solidify so rapidly that the metal has not time to return to its natural crystalline state.

The theory just outlined seems to be supported by examinations of the sprayed deposits, for the structure of the metal coatings and of the whole bodies produced by the Schoop process is always found to be amorphous and vitreous throughout.

This characteristic is of great importance to many large metal industries.

The spray nozzle is provided with three hose pipes which lead oxygen, hydrogen, and air from their respective containers to the burner tube and blast nozzle which are concentric. The cost of operating the Schoop process in the United States has been carefully ascertained through experience with the appliance during the last six months. The seven metals most commonly used for protecting or decorating surfaces are lead, zinc, aluminium, brass, German silver, bronze and copper. When the gases are purchased in small quantities in the usual containers, the cost of spraying lead including the cost of wire, compressed air and labor, is between 1 and 2 cents a square foot and 1 lb. of lead can be sprayed in less than a minute. The other metal coatings vary with the initial price of raw material and its relative hardness.

Where concerns operate a number of pistols they usually generate their own gases or purchase them on a wholesale basis thereby effecting considerable saving in the cost of operating the process.

The spray process may be applied in two entirely different ways—namely, the coating produced may be made detachable or adherent. Accordingly the applications are different.

By means of the detachable sprayed coatings it is possible to copy in metal any metallic, cement or composition object.

On the other hand, permanent coatings are used either for decorative purposes or to preserve surfaces from decay in the atmosphere or from moisture or any form of chemical attack.

Every kind of hardware of iron, steel or alloy at present enameled or dipped or coated with glazes can be plated cheaply with aluminium, tin, or any desired metal. Cooking vessels can be so lined and give better wear than all-aluminium products, at much less cost; steel tanks can be perfectly protected by a lead coating, and vessels liable to rust or to the action of chemicals can be lined cheaply with any desired protection and repaired as quickly.

Every kind of domestic hardware, whether of iron, steel, and any other simple metal, or of alloys, can be coated with a layer of any selected metal, and glass enamel and glazes can also be rapidly applied as lining by the same implements and process. Stoves and utensils of all kinds can be rapidly decorated and protected by sprayed nickel or any other metal desired.

Cooking vessels, both domestic and for manufacture of foodstuffs, can be lined with any metal, and repairing of linings is a rapid, simple process and very inexpensive.

Beer kegs, for instance, requiring frequent and expensive treatment with pitch, can be readily coated inside with aluminium, giving a clean and durable protection, and wines and liquids now subject to leakage and loss in casks can be completely protected by suitable lining in the containers. Brass cloth for chemical plants can be lead sprayed for protection; cast iron pots for alcohol, acid and other stills can be lead lined and all forms of pipes, tanks, reservoirs and containers for acids, oils or chemicals can be protected quickly with any required metal.

Calico printers' rolls can be coated rapidly with homogeneous and adherent copper.

Iron and steel structural work can be provided with a permanent rust-resisting metal coating.

Much of the metal welding can be carried out by the spray process which neither heats nor distorts the object under treatment and is relatively inexpensive.

## Vitreosil

"Vitreosil Apparatus for Chemical Laboratories" is the title of an interesting neatly illustrated pamphlet just issued by the Thermal Syndicate, Ltd., of New York. It contains notes on the various laboratory ware made from vitreosil (fused silica), such as combustion tubes, pyrometer tubes, test tubes, triangles, plates, rods, casseroles, dishes, crucibles, flasks, muffles, trays, etc. An interesting bibliography is added.

In the introduction the general physical and chemical properties of vitreosil are discussed. Vitreosil is 99.8 per cent pure $SiO_2$. Its coefficient of expansion is 0.00000059, that is, it is so small that vitreosil may be subjected to rapid changes of temperature without danger of breakage. It should not be exposed, however, *continuously* to temperatures over 1200 deg. C.

Vitreosil is absolutely insoluble in water. It is unaffected by mineral or organic acids with the exception of hydrofluoric, and at high temperatures, phosphoric acid. The action of phosphoric acid only commences at 400 deg. C., so that for all ordinary work with this acid it can be safely used. Aqua regia or a mixture of chromic and sulphuric acid do not attack vitreosil at any temperature.

Vitreosil resists high temperatures without injury and its insulating value decreases much more slowly with increasing temperatures than is the case with glass or porcelain. These unique properties permit the successful employment of vitreosil as a high-temperature insulator where other ceramic materials are unsatisfactory. It offers the further advantage that moisture does not readily condense on its surface. The translucency of the glazed quality is a valuable property when the material is used in the construction of electrical heating apparatus.

## Niagara Falls Meeting of American Electrochemical Society

The twenty-sixth general meeting of the American Electrochemical Society will be held in Niagara Falls from Thursday to Saturday, October 1 to 3, 1914. Headquarters will be at the Clifton Hotel.

The Board of Directors will meet on Wednesday evening, September 30.

Sessions for reading and discussion of papers on Thursday morning, October 1, and Friday afternoon, October 2 at the Clifton Hotel.

Symposium at the FitzGerald Laboratories, Highland and Vermont Avenues, Niagara Falls, N. Y., Saturday, October 3, morning and afternoon.

*Excursions and Entertainments:*

*Thursday afternoon, October* 1. Excursion to Foster's Flats, Niagara Gorge, a spot not much visited by or well known to tourists. A local authority on the flora, fauna and history of the spot will be present and give information of interest. Light refreshments. This event will be interchangeable with the Professional Session scheduled for Friday afternoon in the event of unfavorable weather on Thursday.

*Thursday evening.* Smoker, "The Home of Section Q." The section has placed a strict censorship on all communications from Niagara Falls relating to the program.

*Friday morning, October* 2. Visits to plants and power houses. A number of interesting plant visits are being arranged and a full list will be announced later. Besides the power houses, the International Acheson Graphite Company and the Niagara Alkali Company, under some restrictions, will be visited. A much larger number of plants will be open to visitors than ever before, this being one of the unusual attractions of the meeting.

*Friday Evening.* Subscription dinner. No speeches. Experimental lecture following.

*Saturday Evening, October* 3. Kommers at Niagara Club or Fort Schlosser Club.

A feature of the meeting will be an Experimental Symposium on "The Practical Side of Electrochemical Investigation," occupying two sessions on Saturday, and consisting of a number of demonstrations of methods and apparatus. Promises of participation have already been secured from Mr. F. A. J. FitzGerald, Research Laboratory General Electric Company, Research Laboratory Westinghouse Electric and Manufacturing Company, Mr. L. E. Saunders, Mr. A. T. Hinckley, Mr. Max Mauran, Dr. Carl Hering and Mr. Lynn Bradley, and others.

The symposium will be held in the FitzGerald Laboratories, where the excellent facilities available will permit a display of extreme interest and of very diversified character.

*Ladies Arrangements:*

All sessions will be open to ladies. On Thursday evening an entertainment will be provided, while members are attending the smoker. The Foster's Flats excursion will be especially interesting to ladies and they are urged to make the trip.

The complete program of papers will be published in our next issue.

---

**The Johnson Electric Smelting, Inc.**, plant will be located probably at Hamilton, Ill., opposite Keokuk on the banks of the Mississippi River. It has been found impossible to procure a suitable site on the Iowa side of the river. The Illinois side is much better from standpoint of favorable freight rates on spelter, copper matte or base lead bullion to New York, Pittsburgh and Chicago. Freight on ores is same from West on either side.

## Personal

Mr. **F. T. Boyer**, formerly connected with the National Lead Company at their Collier works in St. Louis, Mo., is now superintendent of the Philadelphia smelting works of Merchant & Evans Company.

Mr. **J. M. Callow**, of the General Engineering Co., Salt Lake City, has returned west from a trip to New York City.

Dr. **Hector R. Carveth**, works manager of the Niagara Electrochemical Company, tried to get to Europe on the steamship *Kronprinzessin Cecilie* and failed.

Mr. **H. C. Clark**, formerly Ohio agent of the E. F. Houghton Company, is now connected with the Stupakoff Laboratories, pyrometer manufacturers, of Pittsburgh, Pa.

Mr. **George E. Collins** has returned to Denver from London, where he has been on professional business.

Dr. **Stuart Croasdale**, of Denver, is engaged in professional work in British Columbia.

Mr. **F. H. Emerson** has been appointed Boston district manager of the Bristol Company, with headquarters in the Old South Building.

Mr. **C. M. Eye** has been making metallurgical tests at the experimental plant of the Colorado School of Mines, Golden, Col., prior to designing and erecting a cyanide mill for the Benguet Consolidated Company, Bagui, Philippine Islands.

Mr. **Jacob Hasslacher** is convalescing at his summer home in Elka Park, N. Y. On the 8th of August the silver anniversary of the founding of the park was celebrated, of which Mr. Hasslacher is the president. Since Mr. Hasslacher was not well enough to attend the banquet and other festivities, the members and guests of the Park honored their president with an ovation and a long torchlight parade headed by a large brass band. More than two hundred took part, including many engineers and chemists.

Mr. **H. C. Hoover** has accepted the temporary chairmanship of Camp Bird, Ltd., and the Santa Gertrudis Co. Mr. **R. J. Frecheville** has resigned his position as director of the companies and assumes the chairmanship of the technical committee. Messrs. **F. A. Govett** and **F. H. Hamilton** have joined the boards of both companies, and Messrs. **Norman Craig** and **George de Pass** have joined the Santa Gertrudis and Camp Bird boards, respectively.

Mr. **D. C. Jackling** is making one of his periodical trips of inspection to Alaska. From Seattle he will be accompanied by a party of guests on his yacht the *Cyprus*.

Mr. **Lorin Kemp**, until recently in charge of cyanide mills of the North Star Mines Co., Grass Valley, Cal., has resigned to accept a position in Chile.

Mr. **D. J. Lewis, Jr.**, consulting engineer, has just closed a contract with the Cape Cruz Company of New York to furnish for their sugar factory a trap system to collect from their juice heaters, evaporators, vacuum pans and live steam drips, a maximum amount of 100,000 pounds of condensation per hour and return it automatically to the boilers. The pressures will vary on the different devices from zero to 125 pounds. Mr. Lewis was formerly manager of the "Bundy" trap and for three years ending May 1, sales manager and engineer for the Lytton Manufacturing Corporation. He is now associated with Mr. W. J. Wayte, and they are making a specialty of power house, sugar house and chemical works efficiency. Mr. Lewis is sales agent for the Lytton Manufacturing Corporation for New York and New England, and Mr. Wayte is the United States agent for the Watson, Laidlaw & Company, Limited, of Glasgow, Scotland, manufacturers of centrifugal machinery.

Mr. **W. B. Mangan** is manager, and Mr. **W. N. Rossberg** superintendent of the Timber Butte Milling Co., Senator Clark's new zinc concentrator at Butte, Mont.

Mr. **L. M. Marshall** has resigned as assistant general manager of A. J. Haws & Sons, refractory manufacturers, Johnston, Pa. Prior to six months ago Mr. Marshall was chief engineer of the Cambria Steel Company.

Mr. **Kirby Thomas** was in Denver recently on his way to Colorado mining districts on professional business.

Mr. **H. N. Thomson**, formerly with the Anaconda and International smelting companies is at Clarkdale, Ariz., with the United Verde Copper Co.

Mr. **Samuel S. Webber**, of Trenton, N. J., has resigned his position as chief engineer for the Trenton plant of the American Steel & Wire Co.

Mr. **F. S. Youtsey**, of Denver, Col., is at St. Francois, Mo., erecting a mill for the St. Louis Smelting & Refining Co.

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

AQUEOUS BATH (ELECTROPLATING) *Continued*

537,403, April 9, 1895, George D. Burton, of Boston, Mass.

Relates to the extraction of oil and grease from wool. Within a suitable tank, holding about thirty gallons of solution, is placed preferably a solution of bichromate of potash, of specific gravity 1.05; or a solution of five pounds chloride of sodium, three ounces of sulfuric acid, and twenty gallons of water may be used. The wool is now immersed, at first a current of sixty-five amperes at two hundred and twenty volts is passed between electrodes of preferably a foot square. When the desired temperature is reached, the current is reduced to about twenty amperes. The preferred temperature is about 155 deg. F. The oil or grease rises to the surface of the liquid and may be removed; after the wool is sufficiently cleaned, it is removed and washed.

554,795, February 18, 1896, Dexter Reynolds, of Evansville, Indiana, Assignor, by direct and mesne assignments, to T. M. Steinmetz, M. A. Tobin, August Holthaus, and George P. Heckel, of St. Louis, Mo.

Relates to an apparatus to be used in laundering, and is designed to thoroughly cleanse and disinfect wearing-apparel and other fabrics of all disease germs without injury to such fabrics. The apparatus consists of two electrodes, for example zinc, placed in the bottom of the tub, and connected by insulated wires to a suitable source of current. The wires pass through V-shaped flexible tubes that are inserted through the handles of the tub. By subjecting apparel or other fabrics, such as bed-clothes, surgical cloths, bandages, sponges, etc., to immersion in a body of water or other laundering liquid charged with and decomposed by electricity, they are not only thoroughly cleansed, but all disease germs of whatever nature are absorbed and destroyed, thus saving such apparel or fabrics from destruction and rendering them capable of further use. The apparatus is also applicable for sterilizing liquids.

558,176, April 14, 1896, Philip Huber, of Saginaw, Mich.

Relates to an apparatus for decomposing water by electrolysis, and consists of a tank in which are placed bottomless jars having outlets at the top, the outlets being connected to suitable gas receivers. In each jar is placed a platinum electrode. The evolved hydrogen and oxygen may be burned in a suitable burner and heat any object desired, the heated object radiating heat to the surrounding space.

558,717, April 21, 1896, Henry L. Brevoort, of Brooklyn, N Y.; Gertrude L. Brevoort, executrix of said Henry L Brevoort, deceased, assignor by direct and mesne assignments, to the Electro Waterproofing & Dye Fixing Company, of New York, N. Y.

Relates to a process for waterproofing various fabrics made of animal or vegetable fibers, such as threads, cords, ropes, string, cotton sheeting, sails for ships, cloth, etc., made of cotton, wool, or silk. The fabric is wet with water, such as city water, preferably neither acid or alkaline, and pressed between two conductors such as plates or rolls, to give a firm contact. The anode is preferably of aluminium or tin, the cathode may be of the same or different metal, or of carbon. In place of aluminium or tin, iron, copper, or silver may be used as the anode, but these may color the fabric; zinc gives fair results; lead, antimony, or bismuth are not desirable as anodes. On passing a direct current through the wet fabric from anode to cathode, with an ameter in circuit, the instrument will at first indicate a sudden rise in current, which will then drop, due presumably to the formation of oxides, and the presence of gases, and then finally rise again; it should be broken when it rises after the preceding drop. If continued after the second rise, the desired object will be defeated and the goods cease to be water-repellent. After the treatment and the fabric is dried, it will be found to be waterproof, or water-repellent, believed to be produced by a metallic oxide formed from the anode, the oxide entering the fabric or its fibers and making them water-repellent. With cotton cloth, voltages from 1 volt to 100 volts have been used, the time of treatment being decreased with the higher voltages. With electrodes of between 2 in. and 3 in. in diameter, using 30 volts and a pressure of about 50 lb. on the electrodes, satisfactory results have been obtained with treatments varying from one second to thirty seconds, preferably about fifteen seconds. In fabrics heavily dressed with soluble matter, the process is not as satisfactory; in fabrics having a dressing or finish containing grease, the water-proofing is difficult because it is difficult to wet the fabric. It is desirable to cover the cathode with a separate piece of cloth when practicing the process.

558,718, April 21, 1896, Henry L. Brevoort, of Brooklyn, N. Y.; Gertrude L. Brevoort, executrix of said Henry L. Brevoort, deceased, assignor, by direct and mesne assignments, to the Electro Waterproofing & Dye Fixing Company, of New York, N. Y.

Relates to the fixing of that class of dyes in which the coloring principle is in solution in the liquid to which the cloth is subjected, and which coloring principle requires a mordant to fix the same in the goods. Such colors may be fixed by subjecting the goods to a direct current after they have been run through the solution containing the coloring principle, the goods being between a metal plate or roller connected as anode, and a carbon or metal plate or roller as cathode. The current is passed through the goods from the anode to the cathode, the water in the fibers is decomposed, and oxygen liberated at the anode, forming an oxide of the metal which enters into chemical combination with the coloring principle contained in the goods, thus fixing the color as though a mordant had been employed in the old way. With different metals, as anodes, different colors may be produced, and different degrees of color can be obtained by varying the concentration of the dye. Each specific material, its thickness, and the dye employed, alter the current conditions, necessary to fix the color. A metal is necessary as the anode, as the oxide of a metal is the fixing agent for the natural color, the oxide being carried into the fiber. The metals best adapted for anodes are aluminium, tin, zinc, lead, copper, iron, and brass. In general, those metals work best whose oxides form with the coloring principle colored salts. An alternating current may be used if metallic electrodes are used on both sides. Engraved plates or rollers may be used as anodes.

## Book Reviews

**Fabrication de l'Acier.** By **H. Noble.** Second edition, revised and enlarged. Large octavo (15½ x 24 cm.), 632 pages, 86 illustrations; price 26.50 francs, in New York $5.30. Paris: H. Dunod & E. Pinat.

The author was a French steel-works superintendent, and his book is a happy combination of theory and practice. It covers only the manufacture of Bessemer and open-hearth steels, omitting entirely crucible and electric-furnace steel. Considering the field covered, we find the chapter on the general properties of steels too brief, but the rest of the book very satisfactory. The author evidently writes directly from his own experience, and is moderate in his theoretical views, yet clear and practical. Large use is made throughout of metallurgical calculations, applied particularly to the thermal phenomena of the steel manufacture. It is unfortunate that the author has, however, neglected the heat of formation of the slags, in each case; some of them are now known nearly enough to be brought into the calculation. This is but a minor criticism on a book full of first-class, first-hand information, of a kind needed by every steel manufacturer, but especially valuable to the makers of Bessemer and open-hearth steel.

**Elektrochemisches Praktikum.** By **Dr. Erich Muller.** 16 x 22 cm., 224 pages, 73 illustrations; price 8 marks. Dresden and Leipzig: Theodor Steinkopff.

The author is director of the electrochemical laboratory of the Dresden Technischen Hochschule, and his work shows throughout his intimate familiarity with the subject. After describing the sources of current, and apparatus used, the first section covers exercises on fundamental laws, comprising tests of Ohm's law, Faraday's law, conductivity of electrolytes, electromotive forces. The next section deals with separation of metals from solution, under different conditions. A long section comprising 27 exercises then follows, on the preparation of important inorganic compounds, such as caustic alkali, perchlorates, etc. The production of organic reactions is covered in 10 exercises. Electrolysis of fused salts is illustrated by the production of aluminium, magnesium and decomposition of lead chloride; electrothermal processes by the production of carbide ferrochromium and ferrosilicon.

The 69 exercises are fairly well chosen, and always clearly set forth. We would suggest substituting the production of carborundum for that of ferrochromium, since it illustrates a different kind of process; and that of sodium for magnesium, as being more instructive, and valuable for its historical associations.

While the plan and method of presentation are excellent, the choice of the exercises could be improved upon in several instances, as above suggested.

## Chemical Manufacturing Possibilities

One of the big problems which this country faces as a result of the European war is the possibility of producing such chemicals as have not yet been successfully produced here on a large scale in competition with Europe, though their production is technically possible in this country in so far as the raw materials are available. The production of dyestuffs is the most notable example. Two lines of thought suggest themselves in connection with this problem.

The first is that the problem is in no way technical. It is purely economic. To the concise yet exhaustive summary of the situation by Dr. Bernhard C. Hesse in our last issue we have nothing to add here but the advice that those interested in the matter should read it again and again. If they did, there would be less foolish talk of lack of spunk in American manufacturers. What is lacking in reality and what is lacking absolutely is a reasonable guarantee that the enormous investment required will not be a total loss as soon as the war is over and the imported dyes and other chemicals can be put on the American market again at the old prices. It seems too much to hope that the consumer—the American textile industry in the case of dyestuffs—would stick to the more expensive home product for reasons of patriotism. Clearly nothing is left but a high tariff and the certainty that the people at large so thoroughly understand the situation as to guarantee the tariff remaining in force for a reasonably long period.

A second line of thought is whether coöperation with European manufacturers in this matter would not be economically preferable to competition. It is a fact that, as a result of the war, American financiers have discovered that industrial chemistry is more than a string of drugstores and are willing to invest heavily in new American chemical industries. It is also reasonable to assume that European manufacturers are beginning to recognize that they would be better off now if they had American factories, even if they had to operate them under a decided handicap. It would be eminently safe and sane for American financiers and European manufacturers to come together.

## Grinding Ore for Cyanidation

When a metallurgical process becomes as firmly established as in the case of cyanidation, we no longer anticipate great or revolutionary changes to take place in its application. In a degree the method becomes standardized due to long and varied experience. Then the largest opportunity for improvement lies in the alteration of some detail to meet special conditions. This, in turn, results in standardizing the practice in certain countries or localities where special economic or metallurgical requirements have to be met. Thus we distinguish broadly between the combination sand-slime method and all-sliming practice. Differences in detail of both methods arise from the introduction of amalgamation or concentration.

We are pleased to present elsewhere in this issue a novel proposal for the modification of all-sliming as generally practiced. The author, Mr. W. J. Pentland, is an operator experienced in the practice of cyanidation in Mexico, where silver ores have been so successfully treated by that process. His suggestion is not offered as being of broad general application, but rather as a detail susceptible of use in special cases. Essentially it involves the introduction of an agitator in the tubemill-classifier circuit, in order to give the separated and reground sand the special treatment it may require, instead of submitting the entire pulp to a treatment demanded by only a refractory, and sometimes small, portion of it.

As we have pointed out above, the suggestion is in line with the trend of metallurgical development—introducing modifications in detail to meet special needs. In view of the different character of so-called sand and slime produced in crushing, it is easily conceivable that, in some instances, the former may be more refractory and require longer time of contact and stronger solution than the latter. In such a case it would appear rational to provide these conditions, in view of the arguments advanced by Mr. Pentland. The proposal will be of interest to cyanide metallurgists, who are cordially invited to offer discussion on the subject.

## The War and American Radium Industry

The bills introduced in both houses of Congress early this year, providing for conservation of radium-bearing mineral land and participation by the government in the business of producing radium, have been reposing quietly in the proverbial pigeon-hole. Considering the tempest which these measures precipitated for a brief time, the long period of calm that has followed might be considered as ominous of their approaching death due to desertion and neglect. The Senate bill is the poorer of the two, but the House bill could easily be modified and made acceptable.

By reason of various tactics employed to delay consideration of the bills, they lost their place on the calendar; but it is quite certain that they will come up again with the government's conservation measures. So much time has elapsed that the principal reason urged by the proponents of this legislation—conservation of radium in the public domain—is now less apparent than formerly, for the prospectors have long since taken their cue from the agitation last spring and located all the outcropping or known deposits of radium-bearing minerals. Land that would now be affected by withdrawal would probably be difficult to prospect, but there is still a chance for the discovery of mineral on such land.

But the advent of the European war has put a different phase on our radium industry, because the old-world markets are now closed to American ore. In fact, there is no market, and even the largest American producer of carnotite and manufacturer of radium has closed its own mines. This has developed a demand from smaller producers for an American market, and quite naturally they now beseech the government to enter the field, buy ores and make radium. It is rather amusing to observe the change in sentiment among owners of radium-bearing land since last spring. Some of the government's most active opponents at that time are now eleventh-hour converts to the conservation policy and are urging the passage of a bill to authorize federal operation of a plant to produce radium, so that a domestic market shall be created. Petitions from the San Juan district of Colorado have been forwarded to Washington, urging governmental action.

The mill of the National Radium Institute at Denver is in successful operation under the direction of the Bureau of Mines. The fact that the plant is to be doubled in size is an indication that the results obtained in the first unit are satisfactory to the backers of the project. Likewise, the success of the government's technical staff in this instance has stimulated the present reaction of mine owners in favor of federal operation of a custom mill.

Incidentally, it is of interest to the American radium industry to note that S. C. Lind and C. F. Whittemore, chemists in the Denver office of the Bureau of Mines, have just completed a research, noted elsewhere in this issue, that establishes the normal ratio of radium to uranium in carnotite, just as in pitchblende. Former determinations indicated a low ratio in carnotite, and as a consequence some European buyers have insisted on making an allowance for the supposed deficiency. The establishment of the normal ratio will have a beneficial effect on the American industry, for carnotite in Colorado and Utah now constitutes the world's largest known source of radium.

## The War and American Financing Abroad

Immediately upon the outbreak of the European war two thoughts arose in the American mind, first that merchandise exports from the United States would be greatly increased, second, that unless prevented by drastic measures there would be an avalanche of offerings in the American market of domestic securities held abroad. To avoid the avalanche of securities the stock exchanges were promptly closed and efforts were made to hinder the exportation of gold whereby the sale in the United States of foreign held securities might be restricted. To provide for the exportation of merchandise it was everywhere urged that an American merchant marine of large proportions should at once be provided, evidently upon the hasty assumption that the establishment of shipping facilities constituted the greatest desideratum in the new conditions suddenly thrust upon the United States.

Time and reflection have shown both these thoughts to be fundamentally unsound. As to the sale of our securities by foreign holders, no forecast could reasonably be made, for the foreign investors are individuals, not nations. The fact that the earning power of American corporations would be vastly less affected than the earning power of many foreign corporations might or might not dispose the foreign investor to sell the American securities first. As to the exportation of American merchandise, it has been already developed very clearly that it is not lack of ocean carrying facilities but inability of foreign buyers to finance purchases and effect payment through the purchase of exchange or the establishment of New York credit that is restricting our merchandise export movement.

The analysis of the real problem presented is simple, and yet there is evidence that it is not generally understood. We must pay as we go in the future, as we have done in the past, yet we have reached the present time without ascertaining with any degree of accuracy how we have paid in the past.

It is only now that an investigation is being conducted, for by the war condition, into the quantity of American securities held abroad, yet the sale of those securities has been one of the important items in what is called the unseen balance of trade. Estimates, or rather guesses, currently made at wide ranges on either side of five billion dollars prove how vague has been our information in the past. While we may soon ascertain the volume of American securities held abroad at the present time, we have missed the opportunity of knowing what the volume has been at various times in the past, and thus we are unable to study intelligently the course of our foreign trade. We have paraded figures of the value set upon merchandise, gold and silver exports and imports for many years, apparently ignoring the fact that precise information on these heads is practically valueless unless we know also the items constituting the invisible balance, freights paid for foreign vessel owners, expenditures of American tourists abroad, remittance from the United States of foreign born workmen, premiums paid to foreign insurance companies and various other items, but perhaps the most important of all, the flow of securities and the interest and dividends paid upon them to foreign holders. If we had all the items in the visible and invisible balances of trade they would, of course, balance to a cent, but we lack accurate information upon so many of the items that we cannot even strike a balance by difference, representing some single unknown difference.

It is no less than a public calamity that we do not know how the ledger stands at this tremendously critical juncture. If we had this information we could do with confidence much that we may now shrink from doing even as an experiment. What is left us in our ignorance is merely to endeavor to guess how new items will be added to the ledger in the future. We expect our merchandise imports to be decreased, and we hope that our merchandise exports will be increased. Obviously we cannot expect settlement in gold. From the resumption of specie payments in 1879, through the year 1896, we had net gold exports of $130,000,000, being unable, to that extent, to retain the gold we had plus our own current production. From 1897 to date we have had net gold imports of $290,000,000, and so greatly did the tide turn in our favor that we cannot export any further change of importance, which would bear any measurably important relation to our merchandise movement, seeing that of late our annual merchandise movement has been measured in billions, more than two billions of exports and one and a half billions of imports.

Further prospective changes in the additions to our ledger account are reductions in the expenditures of American tourists abroad and in payments of freight charges to foreign vessel owners. With an increase in the favorable balance in merchandise, in what item is the final settlement to be made? Obviously, in the return of our securities held abroad, or in our purchase of foreign securities. By as much as our securities are returned, by so much will interest and dividend payments to foreign holders be reduced, thus adding annually to the amount that must be liquidated.

It has became well recognized in recent weeks that for foreign countries, particularly South American countries, to buy our goods, their projects must be financed. The financing can no longer be done in Europe. Thus far the current thought seems to be that this constitutes a painful necessity, one that we may not be able to meet. Instead, the view should be that this constitutes a welcome opportunity. The trends of trade should be such as to enable us to do this financing, and gradually to become, instead of a debtor nation, an investor nation. Occasionally our mining and metallurgical experts have gone forth from the country and upon developing a prospect in some foreign land have gone to England or the Continent for the funds necessary to develop it. Obviously the expert's standing in the foreign money marts has been less secure than that of foreign experts, dealing with their own countrymen. A new era in the progress of the United States has now arrived, and the American expert who develops opportunities for profitable devolpments in new countries should be able to find the needed capital at home.

American bankers, who have been so woefully narrow minded as not even to ascertain the volume of American securities held abroad, should reform instantly and post themselves as to what is going on in the world. Wonderful opportunities lie before them as to development in South America and elsewhere, and the trends of commerce in the next few years are going to place in their hands large funds for which it will be their duty to find profitable investment. If the opportunities are properly grasped, confidence in the future of American industry and finance will operate very largely to deter foreign holders from returning our securities to us. Such as are offered at bargain prices should be gladly bought. The question should not be how we can avoid buying them, but how we can buy them to our profit, or become so prosperous that they will not be offered. Courage, rather than fear, should be the spirit in which the problem is attacked.

### The Dependence of Industries on Chemistry

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—"It is, however, unfortunately to be feared that a very large number of lines of manufacture will probably have to depend upon the chemical industry for advice and technical assistance."

What horrid treason is this that rears its head in the editorial pages of *Metallurgical and Chemical Engineering,* of all places? Is it a misfortune to be obliged to depend upon the "chemical industry"? That is a question I cannot answer. But I can speak for a company that depends very largely upon the chemical *profession,* and to those who are facing a similar fate I send a word of cheer and encouragement. It is not a fate so sad as to be unendurable; in fact one grows to like it, though shirt-sleeved plant managers tear their hair and declaim that "a lot of damn high-brows are running the company."

More seriously speaking, will it not be a very good thing for American industry if, owing to the exigencies of the European war, the rule of chemical reason is substituted for the rule of thumb? And will not the same circumstances lead to the perfection of many processes that have not been made "commercially available" heretofore because it was easier or cheaper to depend upon Europe?

Notwithstanding all of the above, the writer perfectly appreciates the whimsical sarcasm of the sentence quoted above from your September editorial on The European War.

D. T. PIERCE.

The Barber Asphalt Paving Company,
Philadelphia, Pa.

### Railroad Electrification as a Relief of Economic Stresses

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—We all know and are keenly and painfully aware that this is a time of stress even in the United States. But fortunately our people are sinking individual differences and exhibiting a spirit of co-operation and there is true leadership by our big men, who rule not by divine right of natal succession but by the noble divine right of ability. To enable some such men to consider an idea of mine which I trust will be practicalized in some way for common good, I submit to the perusal of your readers the following proposal and argument thereupon.

Public financial opinion is right fearful and apprehensive about three things in main. These are the disposal of the cotton crop, the copper industry, and the possibility that several billion dollars' worth of railroad securities will be dumped on our stock market. Other disturbing factors are small compared with the above big three. In 1893-6, municipalities put unemployed artisans to work on the public roads. These men were not bums but good, earnest men, who wished to work. My idea is that we should adopt a similar scheme—only in a scientific, efficient, and national manner—that is, that by energetic methods we should start next spring the electrification of such portions of our railroads as are clearly to be benefited thereby.
